SUMMARY

Our understanding of the evolution, formation, and pathological disruption of human brain circuits is impeded by a lack of comprehensive data on the developing brain transcriptome. A whole-genome, exon-level expression analysis of 13 regions from left and right sides of the mid-fetal human brain revealed that 76% of genes are expressed, and 44% of these are differentially regulated. These data reveal a large number of specific gene expression and alternative splicing patterns, as well as coexpression networks, associated with distinct regions and neurodevelopmental processes. Of particular relevance to cognitive specializations, we have characterized the transcriptional landscapes of prefrontal cortex and perisylvian speech and language areas, which exhibit a population-level global expression symmetry. We show that differentially expressed genes are more frequently associated with human-specific evolution of putative *cis*-regulatory elements. These data provide a wealth of biological insights into the complex transcriptional and molecular underpinnings of human brain development and evolution.

INTRODUCTION

The human brain is an immensely complex organ composed of billions of precisely interconnected neurons. The increase in both size and complexity of the brain, and in particular of the prefrontal cortex (PFC), defines us as a species more than any other evolutionary event (Kostovic, 1990; Hill and Walsh, 2005; Kaas and Preuss, 2007; Bystron et al., 2008). The development of human brain circuitry depends on the diversity and precise spatiotemporal regulation of its transcriptome. Thus, it has long been postulated that changes in the transcriptional regulation of key developmentally expressed genes contributed signif-

icantly to the evolution of human brain uniqueness (King and Wilson, 1975; Carroll, 2005; Khaitovich et al., 2006; Sikela, 2006; Vallender et al., 2008; Varki et al., 2008). Such changes are thought to have led to the creation of new combinatorial expression patterns from a relatively limited set of genes, and ultimately to the formation of distinct neuronal circuits that fostered the emergence of higher cognitive skills.

One essential mechanism for increasing the spatiotemporal complexity of the transcriptome is alternative splicing (AS), which generates multiple mRNA transcripts from a single gene. It has been estimated that 70% or more of human multiexon genes are alternatively spliced (Johnson et al., 2003) and that the majority of splicing events are regulated in a tissue-specific manner (Clark et al., 2007). Moreover, in the adult human, the brain expresses more alternatively spliced transcripts than any other tissue (Yeo et al., 2004), and the importance of specific AS programs to a number of neurodevelopmental and neurological processes has been recognized (Licatalosi and Darnell, 2006; Coutinho-Mansfield et al., 2007). Perhaps most intriguingly, AS has also been implicated as a significant source of evolutionary diversity between human and chimpanzee (Calarco et al., 2007). Nevertheless, the extent and spatial specificity of AS within the developing human brain have not yet been evaluated.

The evolution of the human brain not only provided us with remarkable cognitive and motor abilities, but might also have increased our susceptibility to a spectrum of neurological and psychiatric disorders. Substantial evidence suggests that the symptoms of many human brain disorders are dramatically influenced by pre-existing regional molecular profiles and neuronal circuitry (Morrison and Hof, 1997). For example, schizophrenia and autism are linked to dysfunction of specific cortical circuits, in particular those of the PFC (Levitt, 2005). This suggests that such disorders are defined in part during development by differential gene expression determining regional differences in neuronal circuits.

Despite these motivations, technological and practical limitations have until now precluded a spatially comprehensive transcriptome survey of the human brain during the prenatal period, when key gene expression differences responsible for the unique

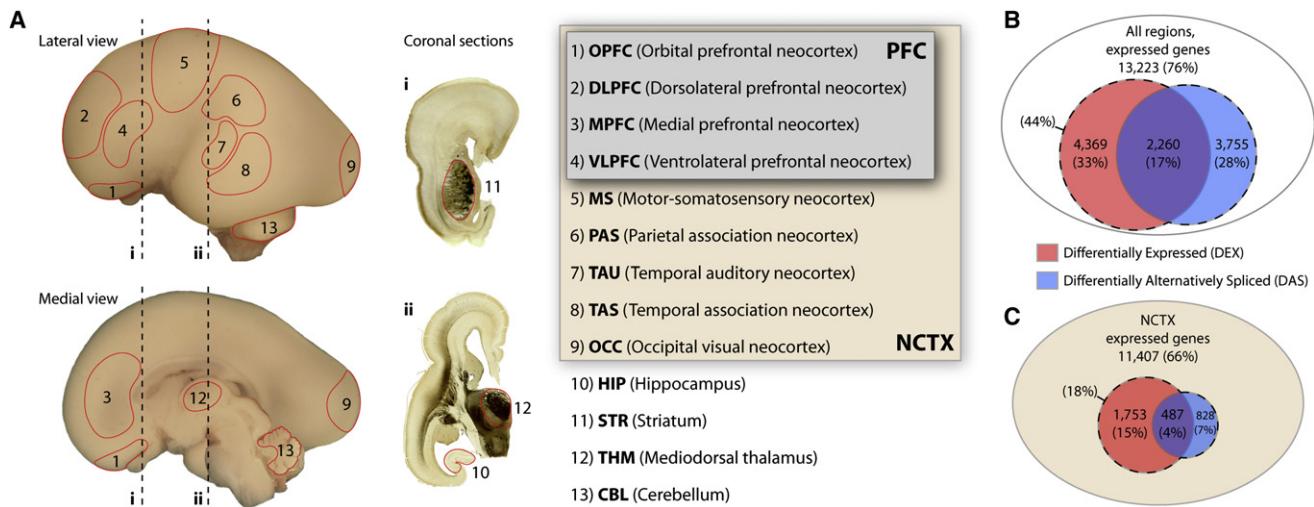

Figure 1. Regional and Neocortical Areal Gene Expression Profiling in the Mid-Fetal Human Brain

(A) Human late mid-fetal brain illustrating locations of tissue samples microdissected from nine areas of neocortex (NCTX; including four areas of the prefrontal cortex [PFC]), hippocampus (HIP), striatum (STR), mediodorsal thalamus (THM), and cerebellum (CBL) from both sides of four mid-fetal brains. Dashed lines (i, ii) indicate levels of acetylcholine esterase-reacted coronal tissue sections.

(B) Comparison among NCTX, HIP, STR, THM, and CBL detected 76% of core genes expressed above background in at least one brain region. At a FDR of 10^{-5} , 33% of these were DEX and 28% DAS between regions.

(C) Intra-NCTX analysis yielded fewer DEX and DAS genes, even at a relaxed threshold (FDR = 0.01).

features of human brain development and evolution are prominent. In this study, we used whole-genome exon microarrays to survey the transcriptome of the human left and right cerebellum, thalamus, striatum, hippocampus, and nine neocortical areas at mid-fetal gestation, a crucial developmental period for the formation of neuronal circuits and the appearance of structural asymmetry in perisylvian neocortical areas. Through multifaceted analysis of these data, we identified regional, intraneocortical areal, and cell type-restricted patterns of differential gene expression, coordinated activity, and AS associated with various neurodevelopmental processes. In addition, we discovered a disproportionate association of differentially expressed genes with conserved putative *cis*-regulatory elements displaying human-specific accelerated evolution. Altogether, these data represent a unique and crucial resource, and provide biologically relevant insights into the genetic and molecular mechanisms underlying the development, evolution, and increased disease susceptibility of the human brain.

RESULTS

Microdissection and Evaluation of Late Mid-Fetal Human Brain Specimens

The late mid-fetal stage is a crucial developmental period encompassing multiple cellular processes that are essential to the development of the human brain (Kostovic, 1990; Bystron et al., 2008; Fertuzinhos et al., 2009), and which have also likely undergone substantial evolutionary changes. The regions depicted schematically in Figure 1A, representing five major embryonic brain regions, were microdissected from left and right sides of four late mid-fetal human brains (18, 19, 21, and 23 weeks of gestation [wg]). Samples included cerebellum

(CBL), thalamus (THM), striatum (STR), hippocampus (HIP), and nine areas of neocortex (NCTX) individually representing the major sensory and association cortices, with the exception of the somatosensory and motor cortices, which cannot be reliably distinguished at this fetal stage and were therefore combined into one “motor-somatosensory” (MS) sample. Furthermore, we sampled four distinct areas of PFC: orbital (OPFC), dorsolateral (DLPFC), medial (MPFC), and ventrolateral (VLPFC). For complete details of tissue sources and specimens, see Table S1 in the Supplemental Data available with this article online.

Tissue remaining after microdissection was fixed and analyzed for possible neuropathological defects and the presence of all major neuronal and glial cell types present at this developmental age (Figures S1 and S2 and data not shown). Genomic analysis with Illumina BeadChip whole-genome genotyping assays confirmed the absence of large-scale genomic structural defects such as aneuploidy. Furthermore, copy number variant (CNV) predictions for all four brains fell within the range of variation found in a sample of 120 well-characterized HapMap individuals, and the majority of predictions corresponded to known CNVs (Figure S3 and Table S2). Thus, by multiple measures, these brains did not exhibit any obvious signs of neurodevelopmental or genetic pathology.

Spatially Comprehensive, Genome-wide, Exon-Level Expression Profiling

We hybridized RNA isolated from the regions illustrated in Figure 1A to Affymetrix GeneChip Human Exon 1.0 ST Arrays (“Exon Arrays”) to obtain independent genome-wide “whole transcript coverage” expression data from each of the four microdissected brains (Table S3). Probesets on the Exon Array

are classified as Core, Extended, or Full according to the level of annotation of the source sequence(s); all analyses reported here utilized only the highest confidence “core” probesets, which are based on RefSeq and GenBank full-length mRNAs. Probesets are grouped into “transcript clusters” corresponding to all possible isoforms transcribed from a single locus or gene; therefore, for simplicity we refer to transcript clusters as genes throughout these results.

Hybridization of selected samples to both Affymetrix U133 and Exon microarrays revealed comparable differential expression results between the two platforms ($R^2 > 0.5$; **Figure S4**). In addition, we performed principal component analysis (PCA) to assess the consistency of Exon Array data within and between brain regions, in comparison to the variability across subjects or hybridizations (**Figure S5**). PCA confirmed that brain region, rather than individual differences, contributed the majority of variance to the data. Together, these results supported the validity of the Exon Array for comprehensive expression profiling of the mid-fetal human brain.

Regional Differential Gene Expression and Alternative Splicing

We first analyzed gene expression and splicing differences across the five major embryonic brain divisions (NCTX, HIP, STR, THM, and CBL) represented in our samples. Out of 17,421 core transcripts, just under 76% (13,223) were present in at least one brain region, indicating that the great majority of human genes are significantly expressed in the developing brain (**Figure 1B**). Moreover, at a stringent false discovery rate (FDR) of 10^{-5} , 4369 genes, or about 33% of those present, were differentially expressed (DEX). In addition, 3755 genes (28%) exhibited differential exon usage suggestive of region-dependent splicing (“differentially alternatively spliced,” DAS), for a combined 44% of expressed genes showing evidence of some form of differential regulation. A total of 2260 genes (17%) fell into both categories (DEX and DAS). Of particular note are 1495 genes, or 11% of those present, detected as DAS but not DEX, which represent a cohort of genes whose differential regulation across brain regions would not be detected by older 3'-biased array platforms. For our purposes, AS encompasses alternative promoter usage, polyadenylation site usage, and cassette exon splicing. Numbers of genes present, DEX, and DAS from all analyses are given in **Table S4**.

To identify candidates for further study, we selected DEX genes ($FDR < 10^{-5}$) with a minimum 2-fold difference in expression between any two brain regions and performed unsupervised hierarchical clustering on both genes and brain regions. We used the resulting heatmaps to identify groups of genes with the most specific or restricted expression patterns (**Figure 2**). In addition to large numbers of novel expression patterns, these clusters included transcription factors whose mouse orthologs are critical for the development of region-specific neuronal cell types, including FEZF2, SATB2, SOX5, and TBR1 in cortex, and TITF1 in STR (Sur and Rubenstein, 2005; Chen et al., 2005; Mo-lyneaux et al., 2007; Leone et al., 2008; Britanova et al., 2008; Kwan et al., 2008). This validates our approach to identifying region-specific expression patterns in the developing human brain. Correlations and sizes of these and all subsequent clusters

are given in **Table S5**; complete lists of genes in these clusters are given in **Table S6**.

Consistent with their ontogenetic and phylogenetic closeness and similar cellular composition, NCTX and HIP were the only two brain regions with a positive correlation ($r = 0.13$) across all of the genes clustered, as reflected in the 57 genes in cluster one enriched in both regions (**Figure 2** and **Tables S5 and S6**). CBL was the most distinct of the brain regions sampled, consistent with previous findings in the adult human brain (Khaitovich et al., 2004; Roth et al., 2006; see also **Table S11**) and reflecting differences in both its cytoarchitecture and possibly its developmental time course relative to forebrain structures.

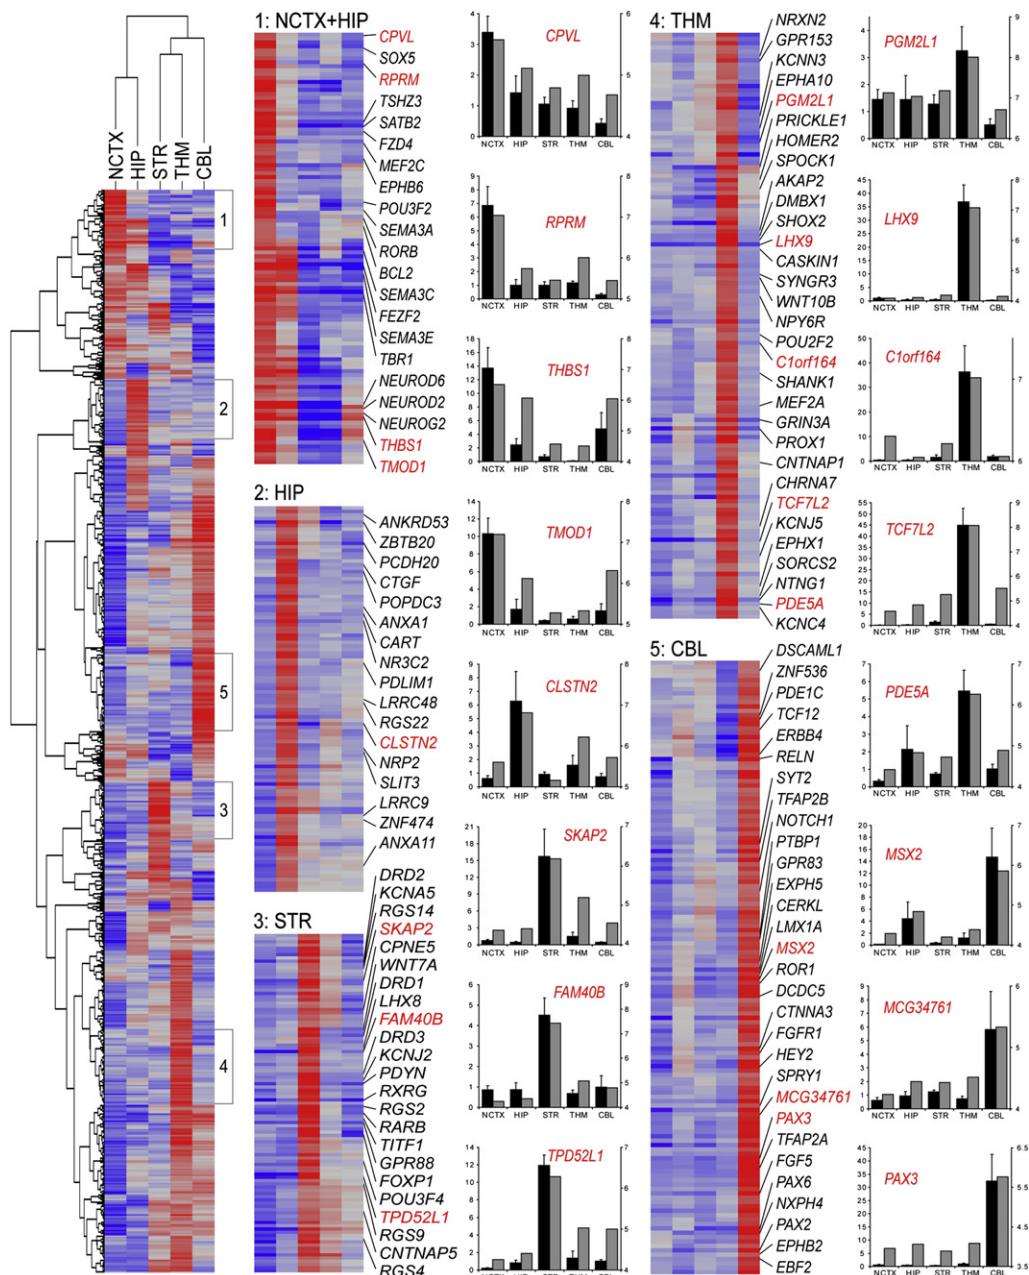

These data provide a survey of the proportions of the human transcriptome with broad or specific expression in the late mid-fetal brain, and identify a large number of regionally enriched or alternatively spliced genes not previously identified as such. In addition, the detection of many orthologs of important rodent neurodevelopmental genes suggests their human counterparts play evolutionarily conserved roles in establishing regional neuronal identity and connectivity.

Validation of Regional Differential Expression Data

We next sought to validate some of these novel expression patterns by additional methods. Genes were prioritized by expression level, fold change, functional classification, and existing rodent and monkey data. Particular emphasis was placed on previously unknown or uncharacterized genes, and on those that appeared to differ in their regional enrichment from available data in other species. A total of 65 of 68 genes validated by quantitative real-time reverse-transcriptase polymerase chain reaction (qRT-PCR) (bar graphs in **Figure 2**; **Tables S6 and S9**) correlated with Exon Array data (median $r = 0.95$), giving us extremely high confidence in Exon Array gene-level analysis. We further examined over 20 candidate genes by *in situ* hybridization (ISH) or immunohistochemistry (IHC) in whole sagittal or coronal sections of 13 additional mid-fetal human brains (**Tables S1 and S6**, **Figure S6**, and additional data available at www.humanbrainatlas.org). These confirmation data provide further confidence in the Exon Array platform, and identify an initial cohort of strong candidate genes for functional analyses.

Genetic Patterning of the Developing Human Neocortex

Next, we used a similar approach to search for areal differences in gene expression and splicing within the NCTX. Previous studies have found few differences between adult human neocortical areas (Khaitovich et al., 2004; Roth et al., 2006). We hypothesized that developing NCTX would show more genetic differences, both because of the possibility of an increased number of genes expressed during development and because of the neuronal differentiation and establishment of connectivity that occur during the late mid-fetal period. Comparing among nine areas of NCTX and using the same FDR threshold as the previous analysis (10^{-5}), we identified 471 DEX (4.1%) and 496 DAS (4.3%) genes from the total of 11,407 expressed (**Table S4**). We hypothesized that important gene expression differences among neocortical areas might be smaller in magnitude than those between brain regions, and thus relaxed the FDR to 1% for exploratory cluster analysis,

yielding 1,753 DEX (15.4%) and 828 DAS (7.3%) genes (Figure 1C). Clustering revealed a clear division between the four PFC areas and the four non-frontal lobe areas (PAS, TAU, TAS, OCC) (Figure S7). Interestingly, the MS area, which was dissected from the border region of the frontal and parietal lobes, was not highly correlated with either prefrontal or nonfrontal

areas. Rather, genes enriched in MS were roughly evenly divided into those correlated with PFC and those correlated with more posterior cortical areas (Figure S7), consistent with the mixed frontal/parietal nature of the tissue sample.

In order to investigate both PFC- and non-frontal-enriched genes in greater detail, we performed two additional, targeted

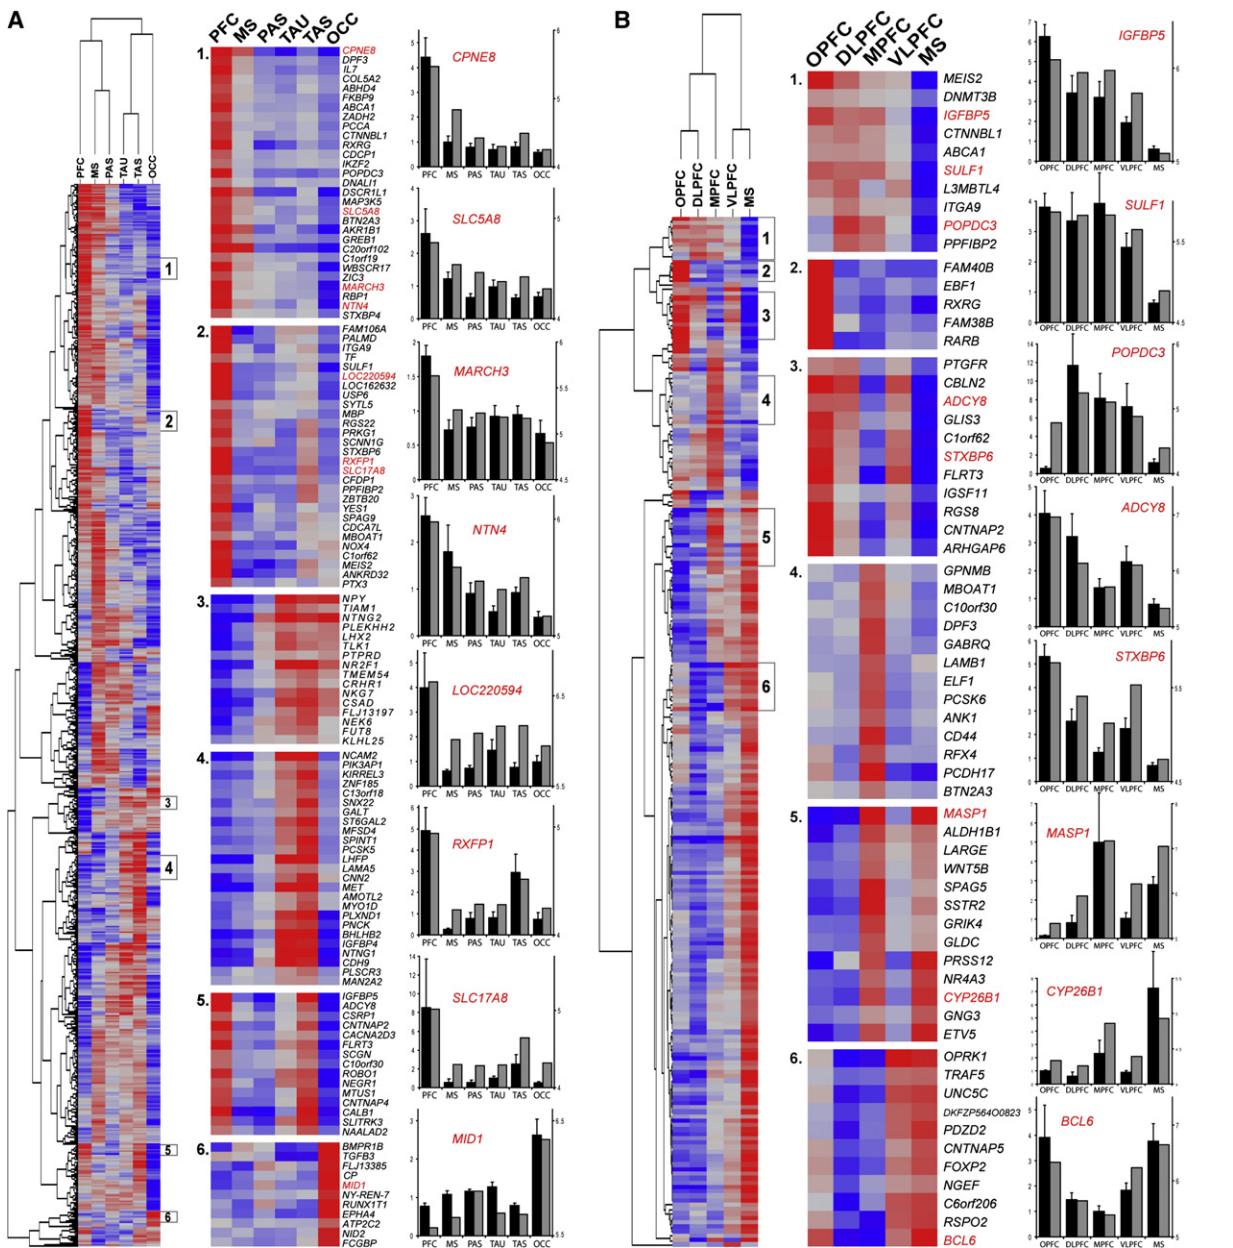

Figure 3. Unsupervised Hierarchical Clustering and qRT-PCR Validation of Selected Genes Differentially Expressed between NCTX Areas

(A) With PFC areas grouped, correlated clusters ($r > 0.8$) of gene enrichment included: (1 and 2) PFC; (3) temporal (TAU + TAS) + OCC; (4) temporal lobe (TAS + TAU); (5) PFC + TAS; and (6) OCC.

(B) We separately analyzed the four PFC areas plus MS, and identified genes enriched within specific frontal lobe areas. Selected clusters include (1) pan-PFC, but not MS; (2) OPFC; (3) orbital and lateral PFC; (4) MPFC; (5) MPFC + MS; (6) VLPFC + MS. Red is higher expression, blue is lower expression. Bar graphs show qRT-PCR confirmation (black bars; mean \pm SEM) next to array data (grey bars) (axes as in Figure 2) with a median ANOVA $p < 0.0004$ and correlation to array data $r = 0.9$. Complete lists of genes in these clusters are given in Tables S7 and S8.

intra-NCTX analyses. First, we grouped together the four PFC samples and compared them to the remaining NCTX areas. Hierarchical clustering of DEX genes (Figure 3A and Tables S5 and S6) revealed, in addition to PFC- and non-frontal-enriched genes, more specific patterns of enrichment including TAU+TAS, PFC+TAS, and OCC. This analysis confirmed previous reports of enrichment of *PCDH17* and *CNTNAP2* (Figure 3B) in mid-fetal

human frontal NCTX (Abrahams et al., 2007) and *EPHA3* and *EPHA7* (Table S9) in the fetal rhesus macaque monkey occipital and temporal NCTX, respectively (Sestan et al., 2001). However, the vast majority of our results revealed a complexity of expression patterns in the developing NCTX that has not been previously recognized in either humans (see Table S11), nonhuman primates, or rodents (see Table S12).

Areal Differences in the Transcriptome of the Developing Prefrontal Cortex

Next, we hypothesized that small but significant gene expression differences might exist among functionally distinct PFC areas during development. Thus, in our second targeted intra-NCTX analysis, we compared the four PFC areas and the MS sample that partially clustered with them (Figure 3B). This analysis yielded 233 DEX genes (2.1% of those present; FDR 1%; Tables S4 and S8), representing evidence for genetic differences between functionally distinct PFC areas in human or non-human primate developing brain. We found the most specific gene enrichment in OPFC, followed by MPFC; other clusters defined various combinations of PFC areas and MS. Interestingly, VLPFC, which encompasses the prospective Broca's speech area and its right hemisphere homolog, was more closely correlated to MS than to other prefrontal areas at this developmental stage ($r = 0.36$), suggesting a molecular similarity to the neighboring orofacial motor cortex controlling muscles involved in speech production. Moreover, genes enriched in VLPFC + MS included *FOXP2* (Figure 3B, cluster 6), haploinsufficiency of which causes a severe speech and language disorder associated with morphological abnormalities and functional underactivation of Broca's area (Lai et al., 2003; Liégeois et al., 2003). This differential expression of *FOXP2* within the human frontal lobe has not been observed in previous studies (Lai et al., 2003; Teramitsu et al., 2004), suggesting that the late mid-fetal stage might be a critical time-point for the role of this gene in establishing speech-related cortical circuitry. In addition, genes that clustered with *FOXP2* might be candidates for further investigation in speech and language disorders (e.g., *CNTNAP5*, *BCL6*, *C6orf206*).

Finally, this result prompted us to search more specifically for genes enriched in the perisylvian cortical region that encompasses future speech and language-related areas: VLPFC, MS, PAS, TAS, and TAU. An analysis contrasting these areas with the remaining NCTX samples identified many slightly but significantly enriched genes (Table S10). *FOXP2* showed a modest 1.1-fold increase in perisylvian areas, whereas the greatest enrichment was found for *TRPC7*, *TRPC4*, and the unknown locus *DKFZp547H025* (1.3- to 1.4-fold enrichment). In addition, *NR4A2*, which was 1.2-fold enriched in perisylvian areas, has previously been found to be enriched in mid-fetal temporal NCTX (Abrahams et al., 2007). These results suggest that despite being dispersed across the frontal, parietal, and temporal lobes, the combined perisylvian cortical areas might express a developmental genetic signature related to their common involvement in speech and language in humans. Altogether, these patterns of expression suggest genetic programs for the development of PFC and perisylvian areas involved in higher cognitive functions, and thus represent promising candidate genes for evolutionary and functional analyses.

Validation and Detailed Cellular Mapping of Intraneocortical Differentially Expressed Genes

Genes identified as DEX within NCTX (Figure 3A) or PFC (Figure 3B) were chosen for further confirmation based on previous association with disorders such as autism, dyslexia, or speech and language impairments (e.g., *CNTNAP2*, *ROBO1*, *FOXP2*; Bakaloglu et al., 2008; Hannula-Jouppi et al., 2005; Lai et al., 2003) or

for apparent divergence from available rodent expression data (e.g., *ANKRD32*, *CPNE8*, *POPDC3*; see Table S12). We validated 75 intra-NCTX DEX genes by qRT-PCR (bar graphs in Figure 3; Tables S7–S9), with a focus on PFC-enriched candidates, again finding a very high level of correlation between Exon Array and qRT-PCR results (median $r > 0.9$; median ANOVA $p < 0.005$). In addition, we confirmed 18 intra-NCTX DEX genes by ISH and/or IHC (Figure 4 and Table S9). These analyses revealed that despite the cellular heterogeneity of NCTX, Exon Array analysis was able to detect areal differences not only in genes exhibiting widespread expression within a neocortical area (Figure 4F), but also in genes whose expression differs in specific cell types, including astrocytes (Figure 4I), subplate neurons and marginal zone cells (Figure 4L), and cortical layer-specific neurons (Figure 4C). Thus, gene expression in various cell types contributes to neocortical areal molecular differences during development.

Global Left-Right Symmetry of Late Mid-Fetal Neocortical Gene Expression

The human brain exhibits structural and functional left-right differences, a prominent example of which is the interhemispheric asymmetry of perisylvian NCTX underlying the functional lateralization in hand preference and speech and language processing (Galaburda et al., 1978). Subtle neocortical structural asymmetries first become evident during the late mid-fetal period analyzed in this study (Chi et al., 1977). Furthermore, a recent study by Sun et al. (2005) identified left-right differences in expression of *LMO4* and other genes in the perisylvian regions of the human neocortex during the early mid-fetal period. To investigate whether such molecular correlates of cortical structural asymmetry persist into the late mid-fetal period, we compared gene expression and alternative exon usage between the left and right cortical hemispheres. Our Exon Array analysis did not detect any population-level hemispheric bias of gene expression or AS in individual neocortical areas or other analyzed brain regions. For example, we analyzed perisylvian areas (VLPFC, PAS, TAS, TAU) involved in speech and language processing, but were unable to detect significant differences either in perisylvian cortex as a whole (Figure 5B) or in individual areas (Figure S8). To further validate these findings, we performed qRT-PCR for over 120 genes displaying nonsignificant trends toward neocortical interhemispheric asymmetry on the Exon Arrays (data not shown). Only four of these genes showed a significant hemispheric bias ($p < 0.05$; *THBS1*, *SUMO2*, *CXorf1*, and *FAM5C*), and all four of these results were driven by large but inconsistent asymmetry in specific neocortical areas, possibly reflecting inter-individual differences in these genes' spatial or temporal regulation. For example, *THBS1*, a member of a gene family implicated in synaptogenesis (Christopherson et al., 2005) and human neocortical evolution (Cáceres et al., 2003), was ~2-fold enriched in the right VLPFC in two of the four brains tested. Overall, our results reveal a population-level global interhemispheric symmetry of gene expression in the late mid-fetal NCTX.

Spatial Regulation of Alternative Splicing

A major advantage of the Exon Array platform is the ability to probe individual exons within a transcript and thus test for

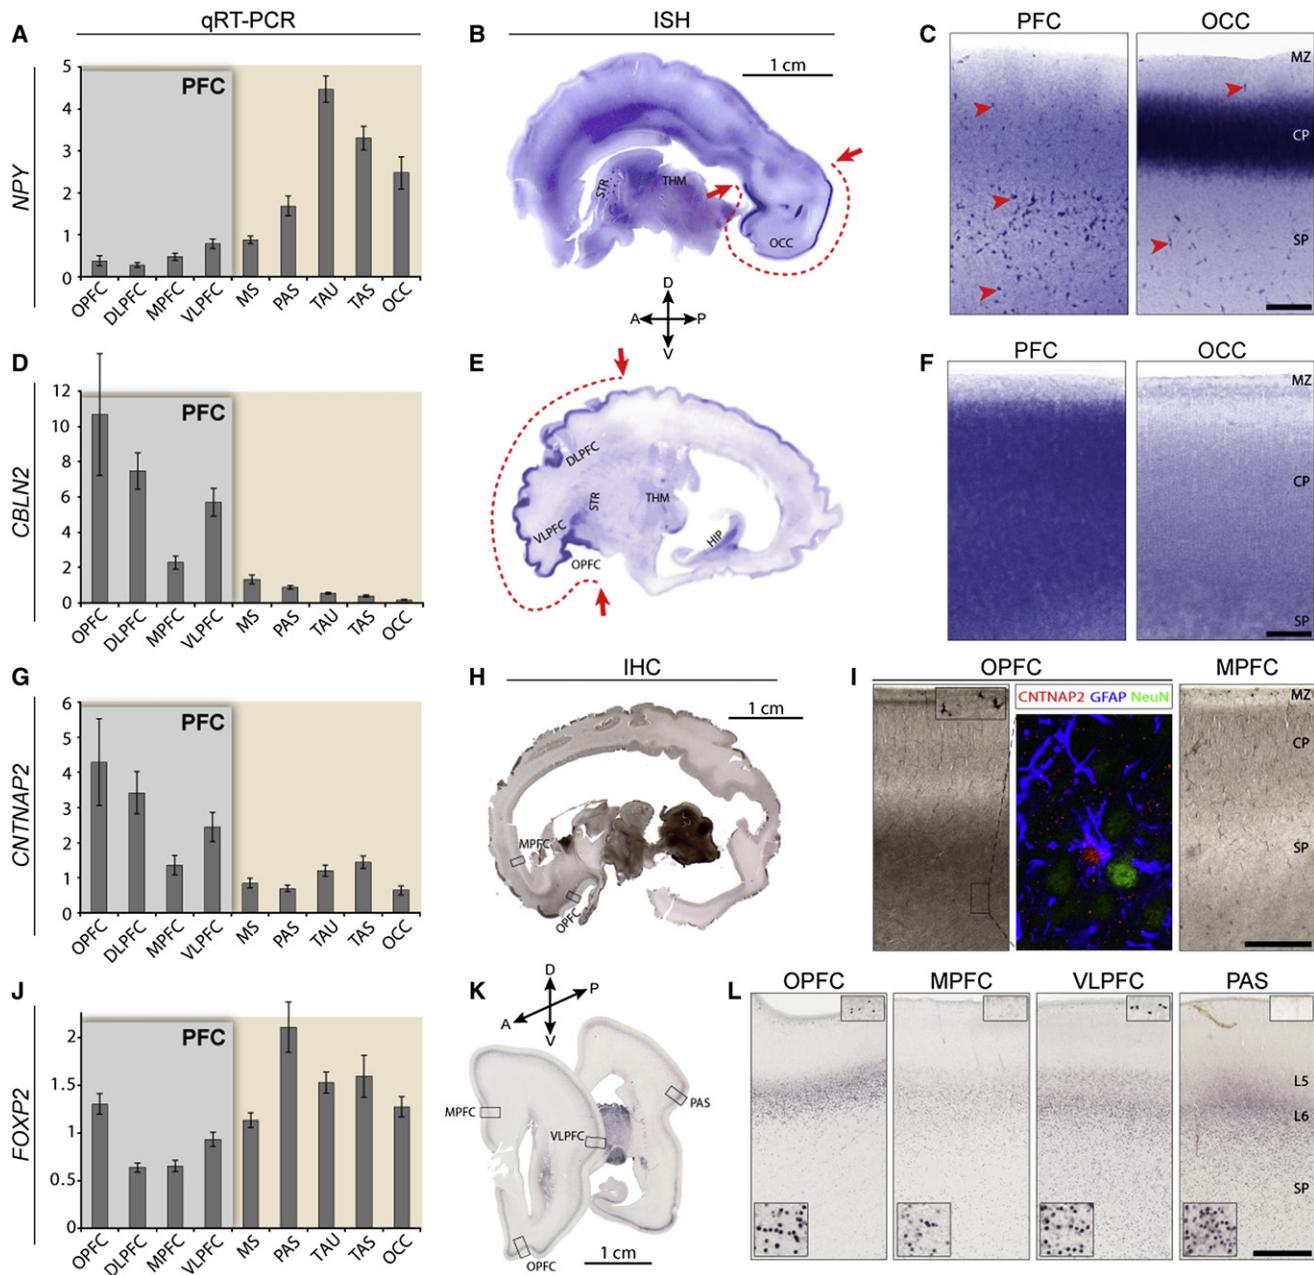

Figure 4. Confirmation and Cellular Mapping of Selected Neocortical Areal Expression Differences

Confirmation of array results by qRT-PCR, and the detection of areal- and cell type-restricted expression patterns by ISH and IHC.

(A–C) NPY enrichment in non-frontal areas is confirmed by qRT-PCR, with highest expression in temporal (TAS, TAU) and occipital lobes (OCC). (B) ISH on a whole sagittal section of 24 wg human brain confirms NPY enrichment in OCC. NPY enrichment in temporal cortex is not visible in this very medial tissue section. (C) Higher magnification reveals specific enrichment in the middle of the occipital cortical plate (CP), and high expression in scattered cells throughout the subplate (SP) (red arrowheads).

(D–F) CBLN2 enrichment in OPFC and lateral PFC is confirmed by qRT-PCR (D) and ISH on a whole sagittal section of 24 wg brain (E). (F) Higher magnification reveals that CBLN2 is enriched throughout the prefrontal CP and SP, but absent from the marginal zone (MZ).

(G–I) CNTNAP2 is selectively enriched in OPFC and lateral PFC areas. (H and I) IHC reveals specific diffuse enrichment in orbitofrontal SP and high expression in scattered MZ cells. Triple-immunofluorescent staining (I, middle panel) reveals colocalization of CNTNAP2 with astrocytic marker GFAP but not neuronal marker NeuN, suggesting differential expression of CNTNAP2 in SP astrocytes.

(J–L) FOXP2 is differentially expressed within the frontal cortex, and enriched in perisylvian cortex. IHC in coronal 22 wg brain sections (K and L) suggests that these differences are accounted for by a combination of higher cellular expression levels in the CP, particularly in OPFC (lower insets), and greater numbers of FOXP2-immunopositive SP cells, especially in VLPFC and PAS. Interestingly, strongly FOXP2-positive cells were present in the MZ in VLPFC and OPFC, but were completely absent from the MZ in other areas (upper insets). Bar graphs are mean ± SEM. Scale bars in (C), (F), (I), and (L) represent 500 μm.

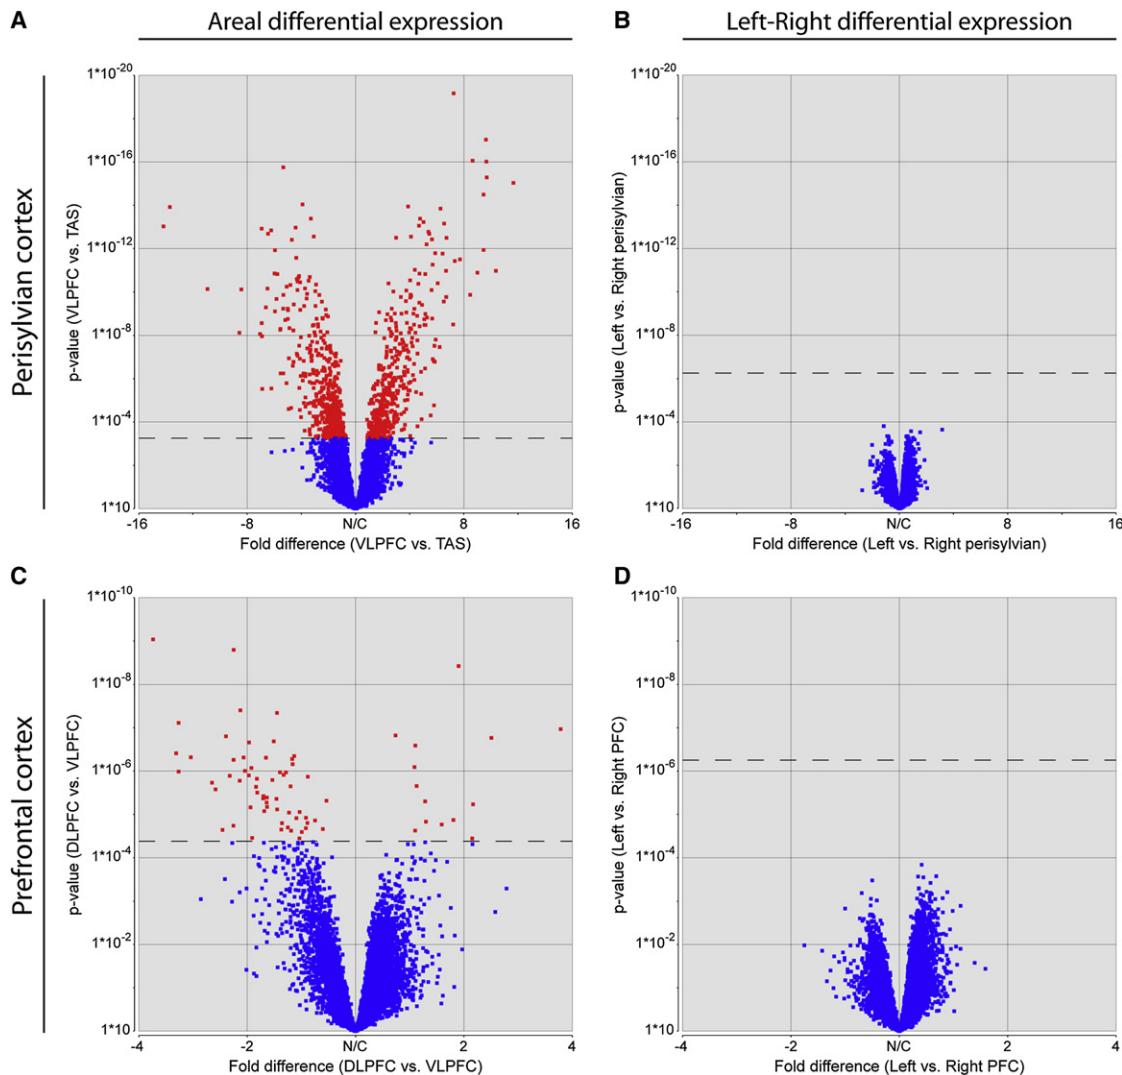

Figure 5. Population-Level Global Left-Right Symmetry of Gene Expression in the Late Mid-Fetal Prefrontal and Perisylvian Neocortex

Volcano plots depicting the range of fold-differences and uncorrected p values in representative perisylvian (A and B) and prefrontal (C and D) areas of NCTX. A large number of genes show significant differences in expression between NCTX areas (A and C). In contrast, no genes showed significant differences between left and right hemispheres within areas (B and D). Dashed lines indicate a corrected p-value of 0.01 (step-up FDR).

tissue-specific expression of alternative isoforms. Analysis of probeset-level expression data identifies genes with a significant interaction between exon expression and tissue as candidates for DAS (Figure S9). From the 28% of genes significantly DAS across brain regions (Figure 1B), we selected a number of promising candidates, some with known alternative isoforms and some previously unknown to be alternatively spliced, and used exon- and isoform-specific qRT-PCR for validation (Figure 6). One of these, *NTRK2*, encodes multiple isoforms, including the full-length *NTRK2a* and the truncated *NTRK2b* (also known as TrkB-T1), which through distinct signaling pathways promote cortical neurogenesis or astrogliogenesis, respectively, in response to BDNF in mice (Cheng et al., 2007). We found that the truncated isoform, *NTRK2b*, is drastically and specifically downregulated in NCTX (Figure 6A), suggesting that the transi-

tion from neurogenesis to astrogliogenesis is delayed in the NCTX compared with other brain regions.

Another DAS gene, *LIMK2*, is one of two LIM kinases that regulate actin dynamics and might be involved in neurite morphogenesis (Endo et al., 2007). *LIMK2* has three known isoforms, at least two of which, *LIMK2a* and *LIMK2b*, are regulated by distinct promoters, encode distinct proteins, and display expression differences between human brain and other tissues (Nomoto et al., 1999). We found that within mid-fetal brain, *LIMK2b* is specifically enriched in THM and CBL (Figure 6B). Although functional differences between these two splice variants have yet to be characterized, region-specific splicing within the developing brain suggests that they might play distinct roles in neuronal morphogenesis. Interestingly, Nomoto et al. (1999) found evidence of a role for RORA in transcriptional regulation

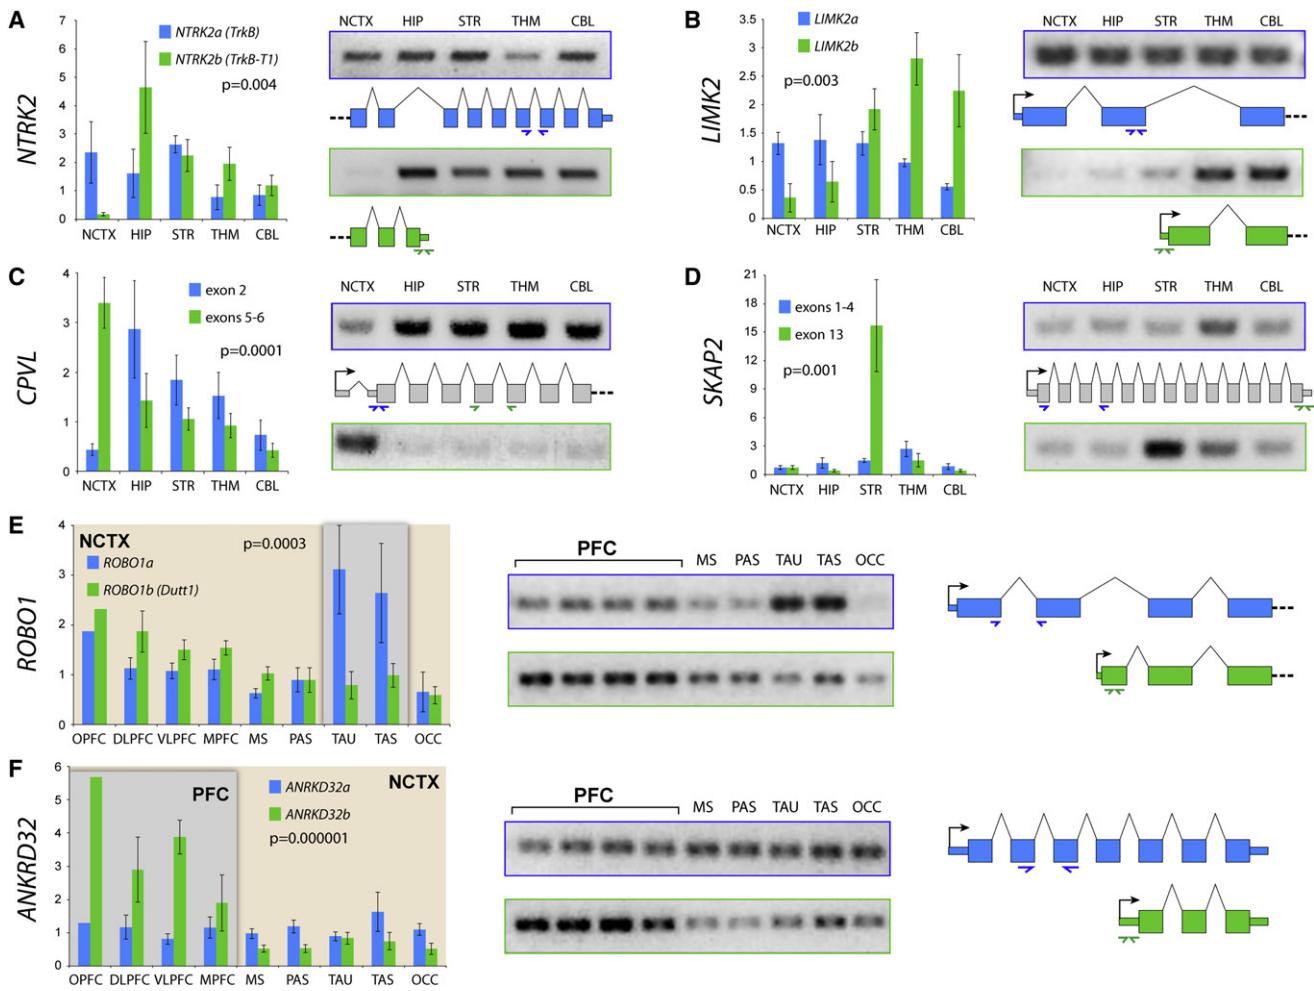

Figure 6. Validation of Selected Region-Specific Alternative Splicing Patterns

Validation of differential AS across brain regions (A–D) or neocortical areas (E and F) by exon- or isoform-specific qRT-PCR.

(A) Confirmation of a specific reduction of truncated *NTRK2b* in NCTX, whereas full-length *NTRK2a* is more evenly expressed throughout the brain.

(B) The *LIMK2b* splice variant, which lacks the N-terminal LIM protein-binding domain, is predominantly enriched in THM and CBL.

(C and D) *CPVL* and *SKAP2* are each predicted to encode a previously unknown short isoform as a result of alternative promoter usage. Exon 2 of *CPVL* is drastically reduced in NCTX, while exons 5–6 are expressed in a complementary pattern (C). A more than 10-fold enrichment in STR of *SKAP2* exon 13 is consistent with expression of a novel variant composed of exons 8–13 (D).

(E) *ROBO1* encodes two known isoforms, the full-length *ROBO1a* and the alternative short isoform *ROBO1b*. In the developing human NCTX, *ROBO1a* is highly enriched in temporal lobe, whereas *ROBO1b* is slightly enriched in PFC.

(F) *ANKRD32* is a previously uncharacterized gene that appears to encode two splice isoforms, *ANKRD32a*, which is evenly expressed across the NCTX, and *ANKRD32b*, which is significantly enriched in PFC. Bar graphs are mean ± SEM. The p values represent the interaction between brain region or NCTX area and splice isoform.

of *LIMK2b*, but not *LIMK2a*. Our data also supported such a relationship, with *RORA* and *LIMK2b* showing parallel enrichment in THM and CBL (Figure S10), suggesting the potential for Exon Array data to help predict transcriptional regulatory relationships at the level of individual splice variants.

We also identified DAS candidates with previously unknown alternative splice variants. For example, Exon Array data indicated differential expression of novel variants of *CPVL* and *SKAP2*, two genes with unknown functions in brain development (Figure S9). Our qRT-PCR data confirmed a specific reduction of *CPVL* exon 2 in NCTX (Figure 6C), and a more than 10-fold enrichment of *SKAP2* exon 13 in STR (Figure 6D).

Together, Exon Array and qRT-PCR data predict novel short isoforms of *CPVL* and *SKAP2* consisting of exons 4–13 and 8–13, respectively, of their full-length transcripts (Figure 6 and Figure S9).

Finally, we identified and confirmed several intra-NCTX DAS candidates. These included *ROBO1* (Figure 6E), a key axon guidance gene whose mouse ortholog is required for the formation of major cortical axonal projections (Andrews et al., 2006). It encodes two main isoforms, *ROBO1a* and *ROBO1b* (*Dutt1*), recently shown to be differentially expressed in the embryonic mouse brain (Nural et al., 2007). We found that human *ROBO1a* is enriched in temporal lobe, whereas *ROBO1b* is enriched in

Table 1. Accelerated Human Evolution of Putative *cis*-Regulatory Elements Near Differentially Expressed Genes

	Nearest to CNSs	Nearest to haCNSs			Nearest to haCNSs but Not caCNSs		
	#	#	%	p Value	#	%	p Value
All human genes	6921	694	10.0%		425	6.1%	
Regionally DEX genes	1263	203	16.1%	2.5E-14	101	8.0%	6.2E-04
Highly expressed, not DEX	1033	70	6.8%	2.1E-05	51	4.9%	0.012
Intra-NCTX DEX genes	1045	181	17.3%	7.1E-16	85	8.1%	9.8E-04
Intra-NCTX high, not DEX	985	81	8.2%	0.006	51	5.2%	0.023

Throughout the genome, 10% of genes nearest to conserved non-coding sequences (CNSs) are near those displaying evidence of accelerated evolution in the human lineage (haCNSs). Genes differentially expressed either within the NCTX or throughout the brain are significantly more likely to be near haCNSs (17% and 16%, respectively). In contrast, genes that are highly expressed without spatial specificity show a slight but significant decrease in association with haCNSs (~7-8%). This trend is preserved when excluding genes that are also near chimpanzee-accelerated elements (caCNSs). The p values represent significance by the hypergeometric distribution of the difference between the observed rate of haCNSs and the rate among all CNS-associated human genes (10%).

PFC (Figure 6E), suggesting that *ROBO1* AS might be involved in patterning human intracortical connectivity.

In addition, many intra-NCTX DAS genes have not been previously characterized. For example, we found that PFC enrichment of *ANKRD32* (Figure 3A, cluster 2) reflects differential expression of a novel short isoform, *ANKRD32b*, whereas full-length *ANKRD32a* is expressed at lower levels uniformly across the NCTX (Figure 6F). Altogether, our evidence for regional differential splicing and predictions of novel isoforms provide insights into specific functional mechanisms of human brain development and suggest a wealth of biological hypotheses for future work. More generally, our Exon Array AS data illuminate a new level of complexity in the transcriptome of the developing human brain.

Regulatory Evolution of Genes Expressed in the Developing Human Brain

Recently, the completed genome sequences of humans, chimpanzees, and other species have been leveraged to identify highly conserved noncoding sequences (CNSs) that often act as transcriptional *cis*-regulatory elements (Pennacchio et al., 2006). A subset of these elements appears to have undergone human-specific accelerated evolution (haCNSs) (Prabhakar et al., 2006). We tested whether DEX genes are disproportionately associated with these haCNSs. We first identified the list of 6921 genes nearest to CNSs, 10% of which are near haCNSs. We found that out of 1045 intra-NCTX DEX genes near CNSs, 181 (17%) were near haCNSs (Table S13a), representing a highly significant enrichment of accelerated evolution in regulatory regions ($p = 7.15 \times 10^{-16}$; Table 1). In contrast, in a control set of 985 genes equally highly expressed in NCTX but with no differential expression across areas, only 8% were found near haCNSs, a significant decrease relative to the genome-wide rate ($p = 0.0056$). Thus, for NCTX-expressed genes, those with differential or restricted expression were twice as likely to be associated with accelerated human evolution of *cis*-regulatory elements. Consistent with this effect, a disproportionate 20% of genes most significantly enriched in perisylvian areas involved in speech and language processing were associated with haCNSs, including *FOXP2*, *PCDH9*, *LPHN2*, and *SORCS3* (Table S10). In order to determine whether this effect was specific to

NCTX or was more generally related to fine spatial control of gene expression during human brain development, we tested the top regionally DEX genes, as well as another control list of highly expressed, non-DEX genes. Again, DEX genes were more than twice as likely to be associated with haCNSs as non-DEX genes (16% versus 7%; Table 1 and Table S13b). Finally, because many genes are also associated with chimpanzee-accelerated CNSs (caCNSs; Prabhakar et al., 2006), we tested whether this trend was preserved among genes near haCNSs but not caCNSs. We again found a significant, though lesser, enrichment of haCNSs near DEX genes (Table 1, right-hand columns). Together, these results suggest that accelerated evolution of putative *cis*-regulatory elements is a feature of a subset of genes with highly specific expression in the developing human brain.

Biological Themes of Differential Gene Expression

To characterize the major biological themes present in regional DEX genes, we assigned Gene Ontology, protein domain, pathway, and other annotations to the five clusters illustrated in Figure 2, and tested for significant enrichment of functionally related terms (Table S14). Not surprisingly, most of the enriched terms involved neural development or function. In the cortex (HIP + NCTX; cluster 1), transcriptional regulation-related annotations were both the most significant (top four terms, all $p < 0.004$) and most numerous (79% of enriched genes). These included transcription factors known to be important in the development of cortical projection neurons such as *FEZF2*, *SATB2*, and *SOX5*, as well as functionally uncharacterized factors such as *TSHZ3* and *ZNF238*. Another overrepresented class of genes enriched in cortex were those involved in axon guidance (e.g., *SEMA3A*, *SEMA3C*, *EPHB6*, *UNC5D*), which might reflect the transition of afferent axons from the subplate to the deep cortical plate at this stage (Kostovic, 1990). In contrast, in STR (cluster 3), the most enriched annotation clusters involved synaptic transmission or specific receptor signaling pathways (e.g., dopamine receptor and GPCR signaling), consistent with the more developed and neurochemically diverse striatal circuits present at this stage (Sajin et al., 1992).

We next annotated the intra-NCTX DEX gene clusters highlighted in Figure 3 and identified similar themes, including signal

transduction, transmembrane proteins, and neurotransmitter receptor activity (Table S14). Notably, there was again a highly significant enrichment of axon guidance-related genes (e.g., *NTN4*, *ROBO1*, *EPHA4*, *PLXND1*, *NTNG1*), consistent with the notion that differences in neuronal connectivity are critical for the definition of distinct functional areas. However, there was little overlap between the axon guidance genes uniformly enriched in NCTX and those DEX between NCTX areas, suggesting that although the former might be responsible for the general establishment of cortical afferent and efferent projections, the latter might be involved in more specific targeting of neocortical area-specific circuitry.

Network Organization of the Mid-Fetal Human Brain Transcriptome

Finally, we sought to go beyond conventional differential gene expression analysis, which alone is not sufficient to convey all of the biological information embedded in large, high-dimensional data sets. We therefore performed weighted gene coexpression network analysis to identify groups of coregulated genes, or “modules,” with similar patterns of connectivity (high topological overlap) (Oldham et al., 2008). We identified modules corresponding to both brain regions, e.g., NCTX and THM (modules M32 and M31; Figure S11 and Tables S15 and S16), and NCTX areas (modules M15 and M24; Figure 7 and Tables S17 and S18). These modules overlapped significantly with DEX genes, consistent with their regional identity. Notably, the two clearest examples of intra-NCTX modules, shown in Figure 7, replicate our earlier finding of a broad PFC-versus-non-frontal division of cortical gene expression profiles (see Figure S7).

Genes with the highest degree of within-module connectivity, termed “hub genes,” are expected to play important functional roles in the biology of the network. Thus, although traditional expression analysis might identify a list of genes, all of which are highly enriched in a given tissue, network analysis provides some insight into which of those genes might be more functionally relevant. In the NCTX module (Figure S11D), hub genes included *ZIC2* and *ZIC4*, genes crucial for midline patterning of the dorsal forebrain (Aruga, 2004); *LRRC7*, a post-synaptic protein involved in dendritic morphology (Quitsch et al., 2005); and *FOXP1*, a transcription factor essential for neocortical specification in rodents (Sur and Rubenstein, 2005) and linked to microcephaly and mental retardation in humans (Shoichet et al., 2005). In the THM module (Figure S11G), the presence of hub gene *TCF7L2*, an important WNT signaling pathway transcription factor (Clevers, 2004), led us to identify 13 additional WNT pathway-annotated genes in the module (Table S16), suggesting a central role for WNT signaling in human THM development.

In the PFC network, hubs included PFC-enriched or -suppressed genes such as *CBLN1*, *RGS8*, and *PART1* (Figure 7D and Table S17), as well as genes of unknown function, such as *LOC400120* (C13orf36), that were not DEX or DAS in any of our conventional expression analyses. Non-PFC network hubs included *MEIS2* and *FGFR1* (Figure 7G), consistent with the roles of retinoic acid and FGF signaling, respectively, in mouse forebrain and neocortical patterning (LaMantia, 1999; Sur and Rubenstein, 2005; Rash and Grove, 2006; O’Leary et al., 2007).

Other modules exhibited no obvious relationship to a particular brain region, and might represent more distributed transcriptional networks important for mid-fetal human brain development. Notably, only two modules, M39 and M41, contained more DAS than DEX genes, suggesting that a common program of AS might contribute to these genes’ transcriptional coregulation. This hypothesis was supported for at least one of these modules (M39; Figure S12A) by gene ontology analysis: the most significantly overrepresented biological process annotations for this module included RNA splicing, mRNA processing, and related terms. Genes in this module included the neuronal-specific splicing factor *PTBP2* (*nPTB*; Coutinho-Mansfield et al., 2007), as well as several HNRNPs, DEAD box, and other splicing factor family genes (Table S19). Although these GO terms also appeared in module M41 (Figure S12B and Table S20), this module was dominated by the more general annotations “RNA metabolic process” and “gene expression,” suggesting a broader transcriptional machinery network. Altogether, network analysis has identified coordinated regulation of gene activity and biological pathways involved in patterning and development of the mid-gestation human brain, elucidating an additional level of complexity in the functional organization of the fetal brain transcriptome. These networks contain mostly uncharacterized transcripts, as well as some key developmental and disease-relevant genes, and provide a rich source of new hypotheses about the functional and transcriptional relationships between genes involved in human brain development.

DISCUSSION

Our genome-wide exon-resolution analysis of the mid-fetal human brain transcriptome revealed complex spatial patterns of gene expression and alternative exon usage, as well as coexpression networks, the vast majority of which have not been previously described. We have found that approximately 76% of well-annotated human genes are expressed at this crucial neurodevelopmental stage. At a conservative false discovery rate of 10^{-5} , 33% of these are DEX and 28% are DAS (Figure 1B and Table S4). The vast majority of these genes have not previously been studied, emphasizing how little is known about the transcriptome of the human fetal brain. Our exploration of these data through various analyses has generated a large number of specific and testable hypotheses with biological relevance to human brain evolution, development, and dysfunction.

Spatial and Functional Organization of the Human Mid-Fetal Brain Transcriptome

These analyses reveal developmental gene expression patterns corresponding to known anatomical and functional subdivisions of the human brain. Although some spatial expression specificities might reflect underlying structural differences, others might reflect transient cellular developmental events, temporal neurogenic and maturational gradients, or spatially restricted signaling centers.

Our analysis has identified more DEX genes in the fetal human brain than have previously been reported in studies of adult

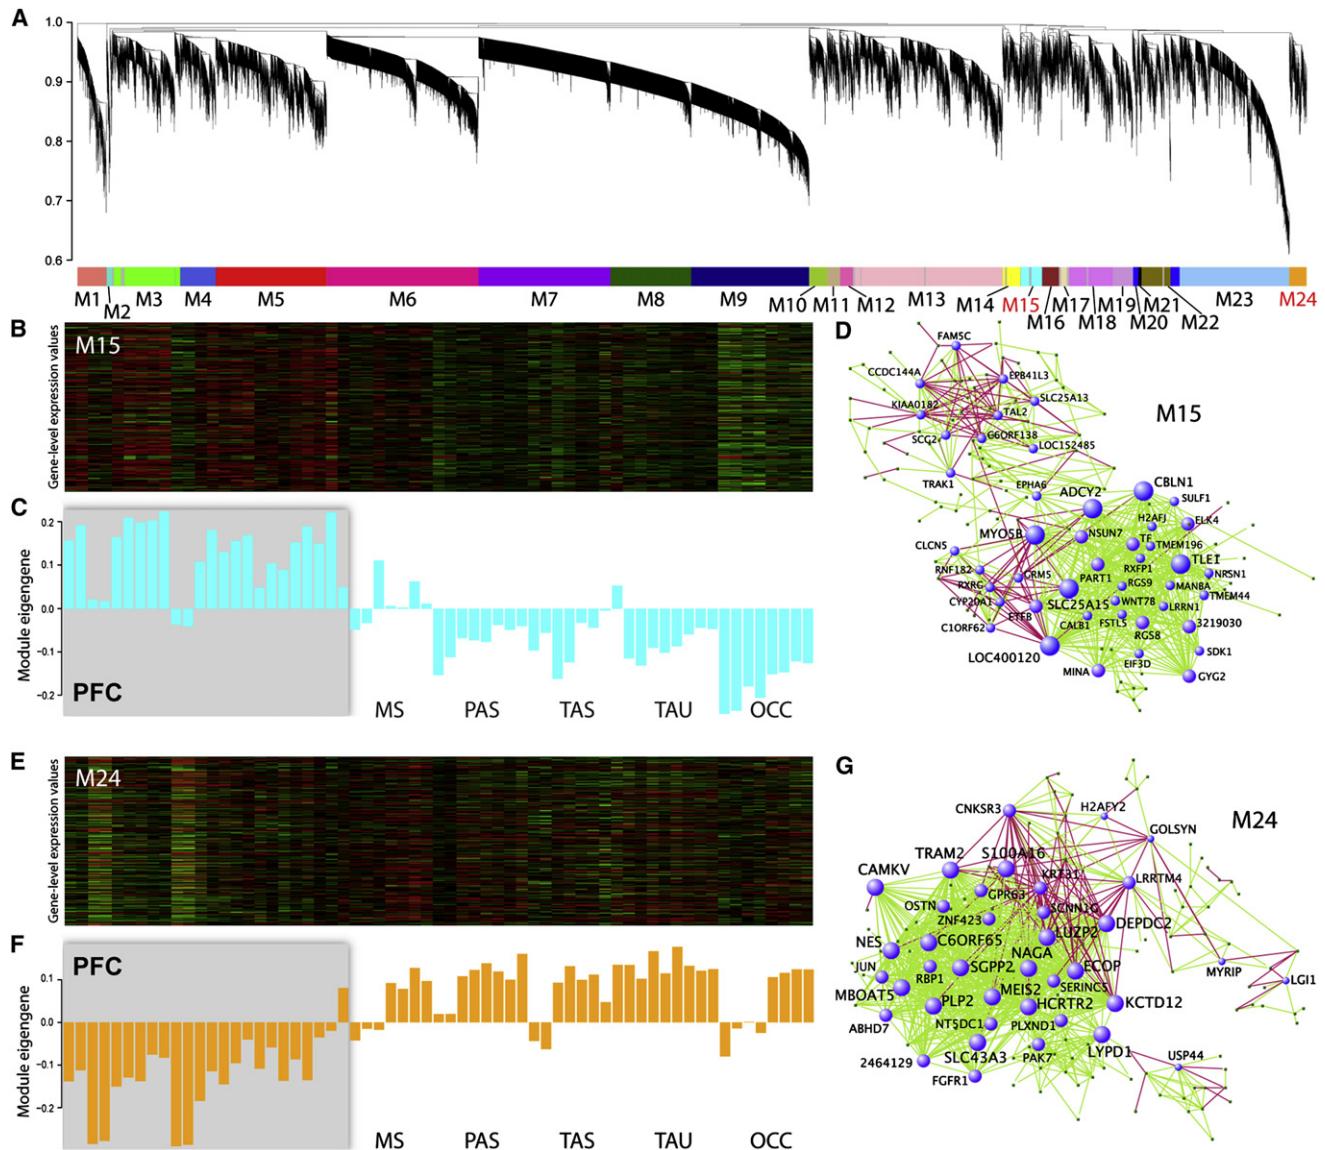

Figure 7. Network Structure of Gene Coregulatory Relationships in Developing Human Neocortex

Network analysis was performed to identify modules of coregulated genes.

(A) Dendrogram showing clustering of genes based on topological overlap to identify modules of coregulated genes in the NCTX. Modules were determined by dynamic tree cutting, numbered, and color-coded.

(B and C) Heatmap (B) and first principal component (C) of expression data for genes in module M15 (cyan) suggest identification of the module with PFC.

(D) The network structure of the PFC module illustrates which genes are the most interconnected. The PFC hub gene *LOC400120* is an uncharacterized locus that was not DEX or DAS by conventional expression analysis. Red lines represent inversely correlated genes.

(E–G) Module M24 (orange), in contrast, corresponds to non-PFC areas. Hubs in this network include known forebrain patterning genes *MEIS2* and *FGFR1*, as well as genes previously unknown or uncharacterized in nervous tissue, such as *TRAM2* and *C6orf65*.

human or embryonic mouse brain (Funatsu et al., 2004; Khaitovich et al., 2004; Roth et al., 2006; Kudo et al., 2007; Mühlfriedel et al., 2007). Multiple factors most likely contribute to this difference, including the increased sensitivity and genomic coverage of the Exon Array and other methodological differences. In addition, due to both the evolutionary differences of neocortical organization between rodent and human (Preuss, 1995) as well as differences in developmental time-points surveyed, the larger

number of DEX genes found in the present study might represent in large part a greater molecular diversity of human cortical areas and cell types. Furthermore, although methodological differences once again contribute, our finding of roughly two orders of magnitude more gene expression differences compared with the adult human NCTX suggests that prenatal differences in gene expression are more robust and complex than those present in the adult human brain.

Global Population-Level Interhemispheric Genetic Symmetry of the Late Mid-Fetal Neocortex

Structural left-right asymmetry is a prominent feature of the human NCTX and first appears during the late mid-fetal stage (Chi et al., 1977; Galaburda et al., 1978). However, we have found global population-level symmetry of gene expression during this period. Using the SAGE technique, Sun et al. (2005) reported significant asymmetric expression of the transcription factor LMO4 at 12 and 14 wg, but this difference was reduced at 16 to 17 wg and not detectable by 19 wg. Together, these data indicate that significant interhemispheric asymmetry of gene expression is likely a transient feature of the embryonic and early fetal NCTX, thus preceding by several weeks the structural asymmetry visible at late mid-gestation. If gene expression asymmetries are present in the late mid-fetal NCTX, they are likely limited to small differences in a few genes, and in a limited set of cell types.

Spatial Regulation of Alternative Splicing

Although the importance of AS in nervous system development has by now been well established, it has not previously been studied on a genome-wide scale in the developing human brain, nor has the prevalence of differential splicing between brain regions been comprehensively addressed. Our study has uncovered spatial patterns of enrichment of both known and novel splice variants. These data include, to our knowledge, the first evidence for intra-NCTX differential splicing, including enrichment of specific variants in the developing human PFC. One example is the axon guidance gene *ROBO1*, which is required for formation of major cortical connections in mouse (Andrews et al., 2006). Interestingly, a translocation breakpoint in the *ROBO1* gene that has been associated with developmental dyslexia, a disorder linked to alterations in cortical circuits, results in loss of *ROBO1a* transcription while leaving *ROBO1b* unaffected (Hannula-Jouppi et al., 2005). In addition, recent work implicates differential splicing of mouse *Robo3* in the midline crossing of spinal cord axons (Chen et al., 2008). Intriguingly, cortical midline (callosal) projections exhibit a rostrocaudal developmental gradient and prominent areal differences in the fetal rhesus macaque monkey (Dehay et al., 1988). Thus, although a role for AS in cortical axon guidance has not previously been identified, our finding of *ROBO1* intra-NCTX DAS, together with several other lines of evidence, suggests that differential areal expression of axon guidance gene splice variants is likely an important mechanism of cortical circuit formation.

Our splicing analysis also identified 19 members of the protocadherin family of cell adhesion molecules (data not shown), consistent with previous reports of extensive splicing in this gene group (Wu and Maniatis, 1999). In contrast, neither *DSCAM*, famous for extensive AS in *Drosophila* (Schmucker et al., 2000), nor the related gene *DSCAML1* appeared to be DAS in our analysis. We expect that the public availability of these Exon Array data will enable discovery and functional analysis of many more AS patterns and variants, generating a more complete picture of the transcriptional and posttranscriptional complexity of the developing human brain transcriptome.

Transcriptional Landscape of the Developing Prefrontal Cortex

We have identified more than 200 genes with putative expression differences within the mid-fetal human frontal lobe, many of which appear to be absent from or uniformly expressed in the developing mouse cortex (Table S12). These expression patterns might reflect species-specific differences in functionally specialized prefrontal areas, such as the complex social and emotional processing of the OPFC, and might also suggest new hypotheses regarding the genetic mechanisms controlling arealization of the human PFC. Many of these genes encode members of the same or related families of proteins (e.g., cerebellins, contactin-associated proteins, and cadherins), suggesting a particular relevance of specific pathways or functions. In addition, several of the genes identified have been previously implicated in disorders that are thought to involve alterations of human PFC circuitry. These include *CNTNAP2*, which is not only related to language delay in autism, but is a target of the language-related transcriptional repressor *FOXP2*, and has a more general role as a susceptibility factor for specific language impairment (Vernes et al., 2008). Our data elaborate on these results, showing specific coenrichment of *CNTNAP2* and *FOXP2* in OPFC and VLPFC. Thus, our study has uncovered complex spatial patterns of gene expression and AS that might reflect the underlying developmental, cellular, and species-specific differences between distinct PFC areas.

Implications for Clinical Research

Our data reveal previously unknown spatial expression patterns for many human disease-relevant genes. Furthermore, our data can help evaluate the results of genome-wide association or linkage studies by narrowing the focus to those genes that are specifically expressed or restricted to a relevant brain circuit during development. Finally, we contribute a rare resource in the form of whole-genome genotyping and expression data from the same individuals (Table S2), enabling correlation of copy number variation to expression levels across different regions of the developing human brain.

Implications for the Genetic Mechanisms of Human Brain Evolution

For more than a quarter century, the hypothesis has been advanced that variation in regulation of gene expression during development, rather than protein sequence, was the dominant factor in human phenotypic evolution (King and Wilson, 1975). In fact, a number of recent comparative studies on the evolution of coding sequences have shown that brain-enriched and brain-specific proteins have evolved more slowly than those enriched in other tissues (Duret and Mouchiroud, 2000), as well as more slowly and more rarely in humans than in other primates (Bakerwell et al., 2007; Wang et al., 2007). Furthermore, consistent with a critical role of regulatory changes in the evolution of uniquely human traits, a number of recent studies have identified signatures of positive selection or accelerated evolution in the human genome in non-coding sequences related to neural development or function (Pollard et al., 2006; Prabhakar et al., 2006; Haygood et al., 2007). Importantly, recent work has demonstrated that the human-specific substitutions in some of

these regions can dramatically alter the spatial extent of their enhancer activity in transgenic mice (Prabhakar et al., 2008). However, the lack of spatially comprehensive transcriptome data from prenatal development, at which time crucial genetic and molecular processes direct the formation of neuronal circuits, has precluded systematic investigation of the relationship between the evolution of regulatory elements and spatial patterns of gene expression in the developing human brain. Our analysis finds that CNSs proximal to mid-fetal brain DEX genes, likely acting in many cases as *cis*-regulatory elements, show a disproportionate frequency of human-specific accelerated evolution (Table 1). Therefore, assuming an initially random distribution of tolerated mutations in CNSs, our results suggest that human-specific regulatory evolution at the level of CNSs has contributed to an increased spatial specificity of developmental brain expression in a subset of genes. This might provide a genetic mechanism for increased expression of human cortical genes (Preuss et al., 2004), mosaic changes in developmental and evolutionary trends confined to specific subsystems, or the emergence of novel phenotypic traits (Rilling and Insel, 1999; Barton and Harvey, 2000; Sherwood et al., 2008). Notably, many haCNS-associated DEX genes are enriched in PFC and perisylvian areas involved in higher cognitive functions (Table S13). Thus, this small subset of DEX genes represents candidates for involvement in critical aspects of human cognitive development and evolution. At the same time, the fact that a great majority of both DEX and non-DEx genes are not associated with haCNSs suggests general genetic and allometric constraints on the developmental trends and coordinated evolution of brain regions (Finlay and Darlington, 1995). These findings are a necessary step in a process that will require comparative analyses with expression data from multiple primate species and developmental time-points, in an effort to elucidate transcriptional mechanisms that led to the phenotypic specializations of human and non-human primate brains.

EXPERIMENTAL PROCEDURES

Human Brain Specimens and Tissue Processing

This study was carried out using postmortem human brain specimens collected from the Human Fetal Tissue Repository at the Albert Einstein College of Medicine (AECOM). Dissected tissue was fresh-frozen in Trizol for RNA and DNA extraction, with a post-mortem interval of less than 1 hr. Remaining tissue was fixed and frozen, and sections were analyzed for neuropathological or developmental defects. Details of specimens, tissue processing, microdissection, and neuropathological assessment are given in Supplemental Experimental Procedures and Table S1. These studies were approved by the Human Investigation Committees of AECOM and Yale University.

RNA Isolation, Processing, and Microarray Hybridization

Total RNA was extracted using TRIzol (Invitrogen), followed by treatment with RNeasy Mini Kit (QIAGEN) to exclude smaller RNAs. The quality of total RNA was evaluated by 2100 Bioanalyzer (Agilent) and RNA 6000 Nano Kit (Agilent) before being processed with the Affymetrix GeneChip Whole Transcript Sense Target Labeling Assay and hybridized to the Affymetrix Exon 1.0 ST Arrays following the recommended Affymetrix protocols. Hybridized arrays were scanned on an Affymetrix GeneChip Scanner 3000 and visually inspected for hybridization artifacts.

Exon Array Data Analysis

Exon Array data were preprocessed using standard RMA normalization, DABG, and probeset summarization methods in either Partek Genomics Suite

(Partek) or the Excel Array Analysis software (XRAY; Biotique Systems). Principal component analysis, left-right hemisphere analyses of variance (ANOVAs), and t tests were performed in Partek using gene summary values for all core transcript clusters. Global DEX and DAS ANOVAs were performed in XRAY using default parameters. All ANOVAs included brain specimen and date of hybridization as cofactors, to eliminate batch effects and variations due to individual genetic differences. All p values were corrected for multiple comparisons using the FDR step-down method. Unsupervised hierarchical clustering was performed in Cluster 3.0 (bonsai.ims.u-tokyo.ac.jp/~mdehoon/software/cluster), and heatmaps were generated using Java Treeview (treeview.sourceforge.net). For further details, see Supplemental Experimental Procedures.

Analysis of Patterns of *Cis*-Regulatory Evolution and Gene Expression

Genomic coordinates of all ~110 k CNSs identified by Prabhakar et al. (2006) were mapped to the human genome (hg18; NCBI build 36.1) on the UCSC Genome Browser (genome.ucsc.edu) and cross-referenced with the RefSeq Genes track using Galaxy (main.g2.bx.psu.edu) to identify the nearest human RefSeq gene to each CNS. After removing duplicates, this yielded 6921 genes, of which 694 were near CNSs reported as showing evidence of accelerated evolution in the human lineage (haCNSs). We then intersected these gene lists with lists of DEX and non-DEX genes, calculated the proportion of haCNSs for each condition, and assigned a p value according to the hypergeometric distribution.

Gene Ontology Annotation Analysis

Annotation analysis was performed using the web-based DAVID software (david.abcc.ncifcrf.gov; Dennis et al., 2003). Intra-NCTX DEX gene clusters from Figure 3 were grouped together to control for the length of annotated gene lists and allow direct comparison with the annotation of Figure 2 clusters. See Supplemental Experimental Procedures for details.

Weighted Gene Coexpression Network Analysis

Network analysis was performed as previously described (Oldham et al., 2008). Annotated R code used for our network analysis is available at www.humanbrainatlas.org. General information on network analysis methodology, as well as WGCNA software, is available at www.genetics.ucla.edu/labs/horvath/CoexpressionNetwork. For further details, see Supplemental Experimental Procedures.

Accession numbers

Microarray data can be accessed through the NCBI Gene Expression Omnibus (accession GSE13344), or viewed as a track on the UCSC Human Genome Browser at genome.ucsc.edu.

Supplemental Data

Supplemental Data include Supplemental Experimental Procedures, 12 figures, 20 tables, and Supplemental References and can be found with this article online at [http://www.cell.com/neuron/supplemental/S0896-6273\(09\)00286-4](http://www.cell.com/neuron/supplemental/S0896-6273(09)00286-4).

ACKNOWLEDGMENTS

We thank Bradford Poulos for assistance with tissue acquisition, Aiping Lin for help with microarray platform comparisons, James Noonan for advice on analysis of haCNSs, Fuying Gao for statistical analysis, Donna Karolchik and Andy Pohl for assistance in creating tracks for the Genome Browser, and many colleagues for their help and comments. Supplemental Experimental Procedures

Supplemental References

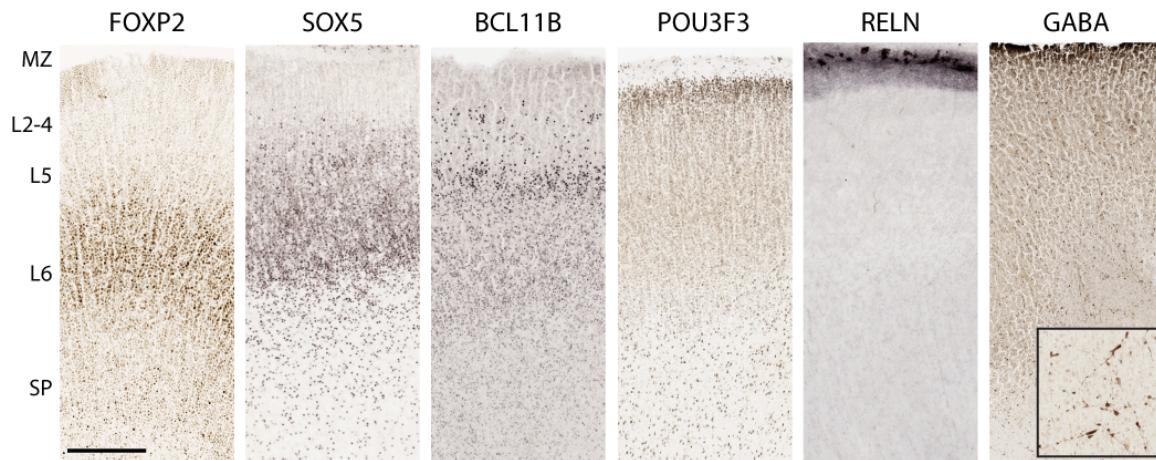

Supplemental Tables

Supplemental Figures

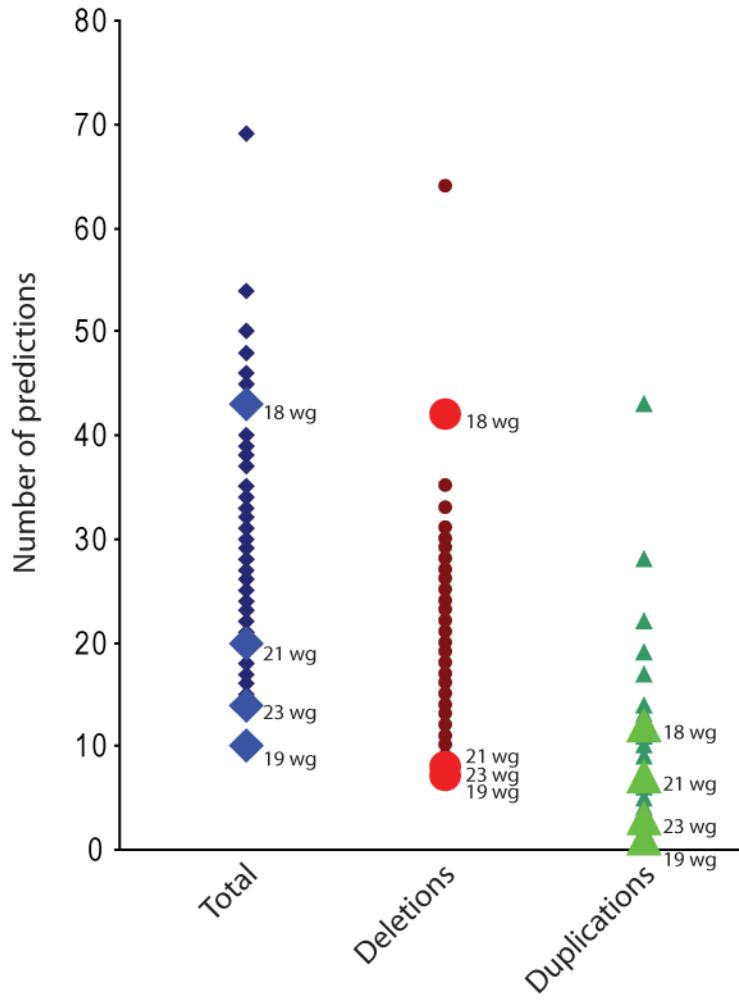

Supplemental Figure 1. Normal Cytoarchitecture of Brain Specimens Used for Exon Array Analysis

Nissl staining of the tissue remaining after microdissection from all four brains used for microarray analysis (specimens 1-4), confirming normal cytoarchitecture and the absence of microscopic neuropathological defects such as periventricular lesions commonly present at this developmental stage. MZ, marginal zone; CP, cortical plate; SP, subplate; SVZ, subventricular zone; VZ, ventricular zone. Scale bar, 250 μ m.

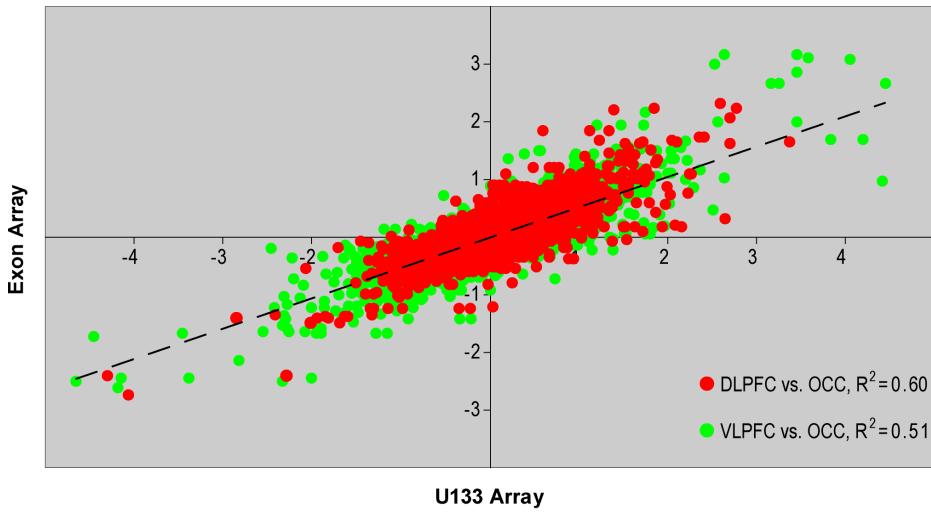

Supplemental Figure 2. Normal Laminar Position of Cortical Neurons in Brain Specimens Used for Exon Array Analysis

Various immunohistochemical markers were used to confirm the presence of all major neuronal and glial cell types present at this developmental age in all four brains. Shown here are selected examples of immunohistochemical staining for markers of layer selective of projection neurons (FOXP2, SOX5, BCL11B, and POU3F3), MZ Cajal-Retzius neurons (RELN) and interneurons (GABA) in the neocortex of the 19 wg brain. The normal laminar position of these neurons indicates absence of obvious defects in neuronal specification and migration. Scale bar, 250 μ m.

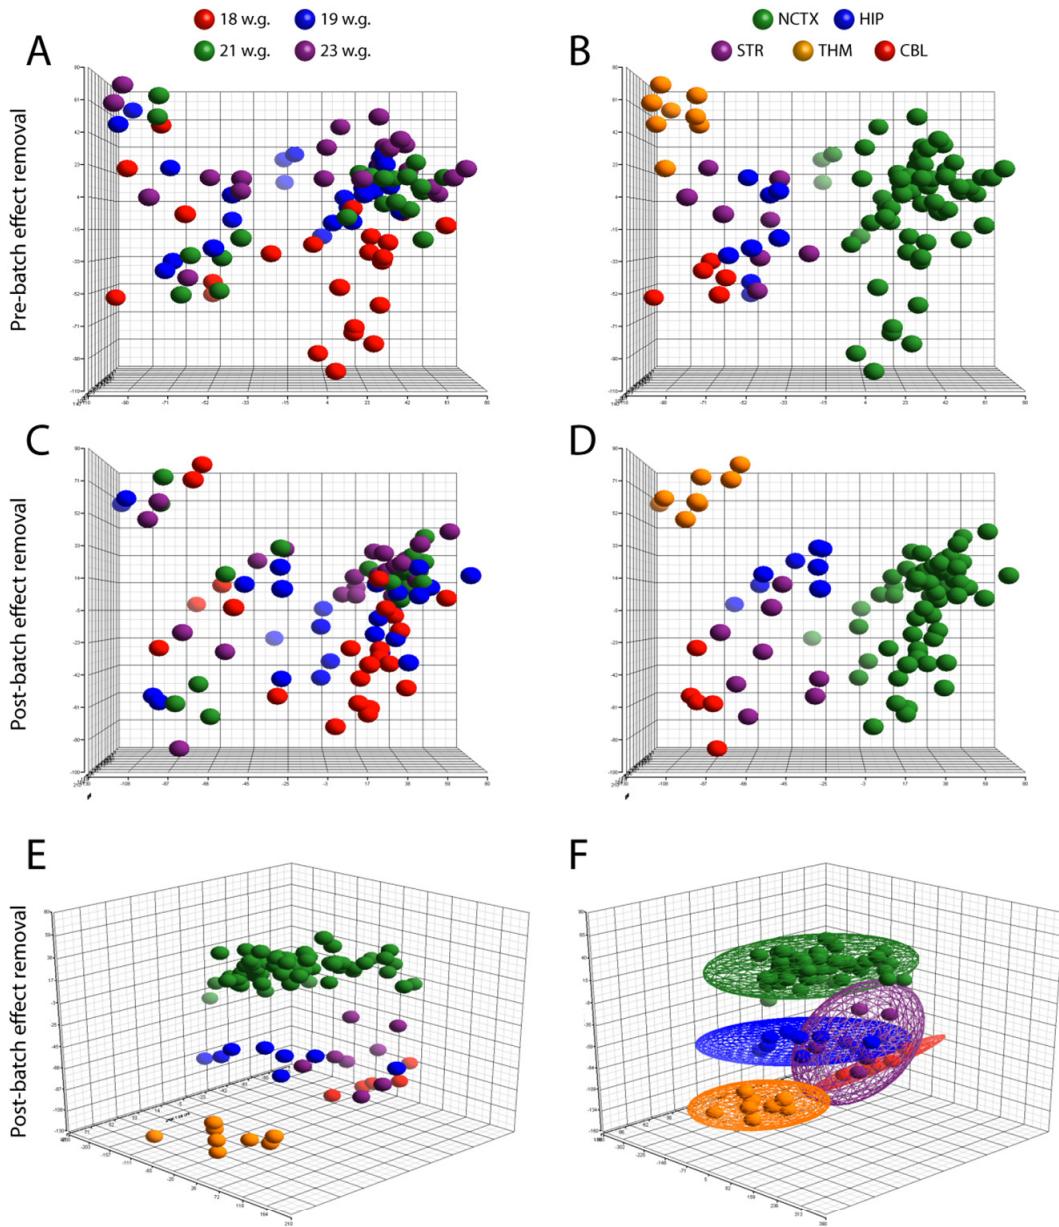

Supplemental Figure 3. Predicted Rates of Copy Number Variation in Brain Specimens Used for Exon Array Analysis

Illumina genotyping microarray data were analyzed for putative copy number variations (CNVs) using the PennCNV algorithm (Wang et al., 2007). We found a total of 88 predicted CNVs, with a median 17 CNVs per individual (Table S2). To place these predictions in the context of expected human genetic variation, we used the same algorithm to analyze 120 well-characterized HapMap samples. We found that predicted CNV rates from our samples (large blue diamonds) fell within the range of expected CNVs per individual (small blue diamonds), and this remained true when predictions were partitioned into putative deletions (red circles) and duplications (green triangles). One brain (18 wg) displayed a higher rate of predicted deletions, but only one predicted duplication; this was likely an effect of a slightly lower call rate on this chip (95%), which may have been due to DNA sample degradation or technical error in the chip. All other call rates were above 99%. Finally, the majority (59%) of predicted CNVs in our samples overlapped known CNVs or segmental duplications, further indicating that these brains were within the normal range of human genetic variation.

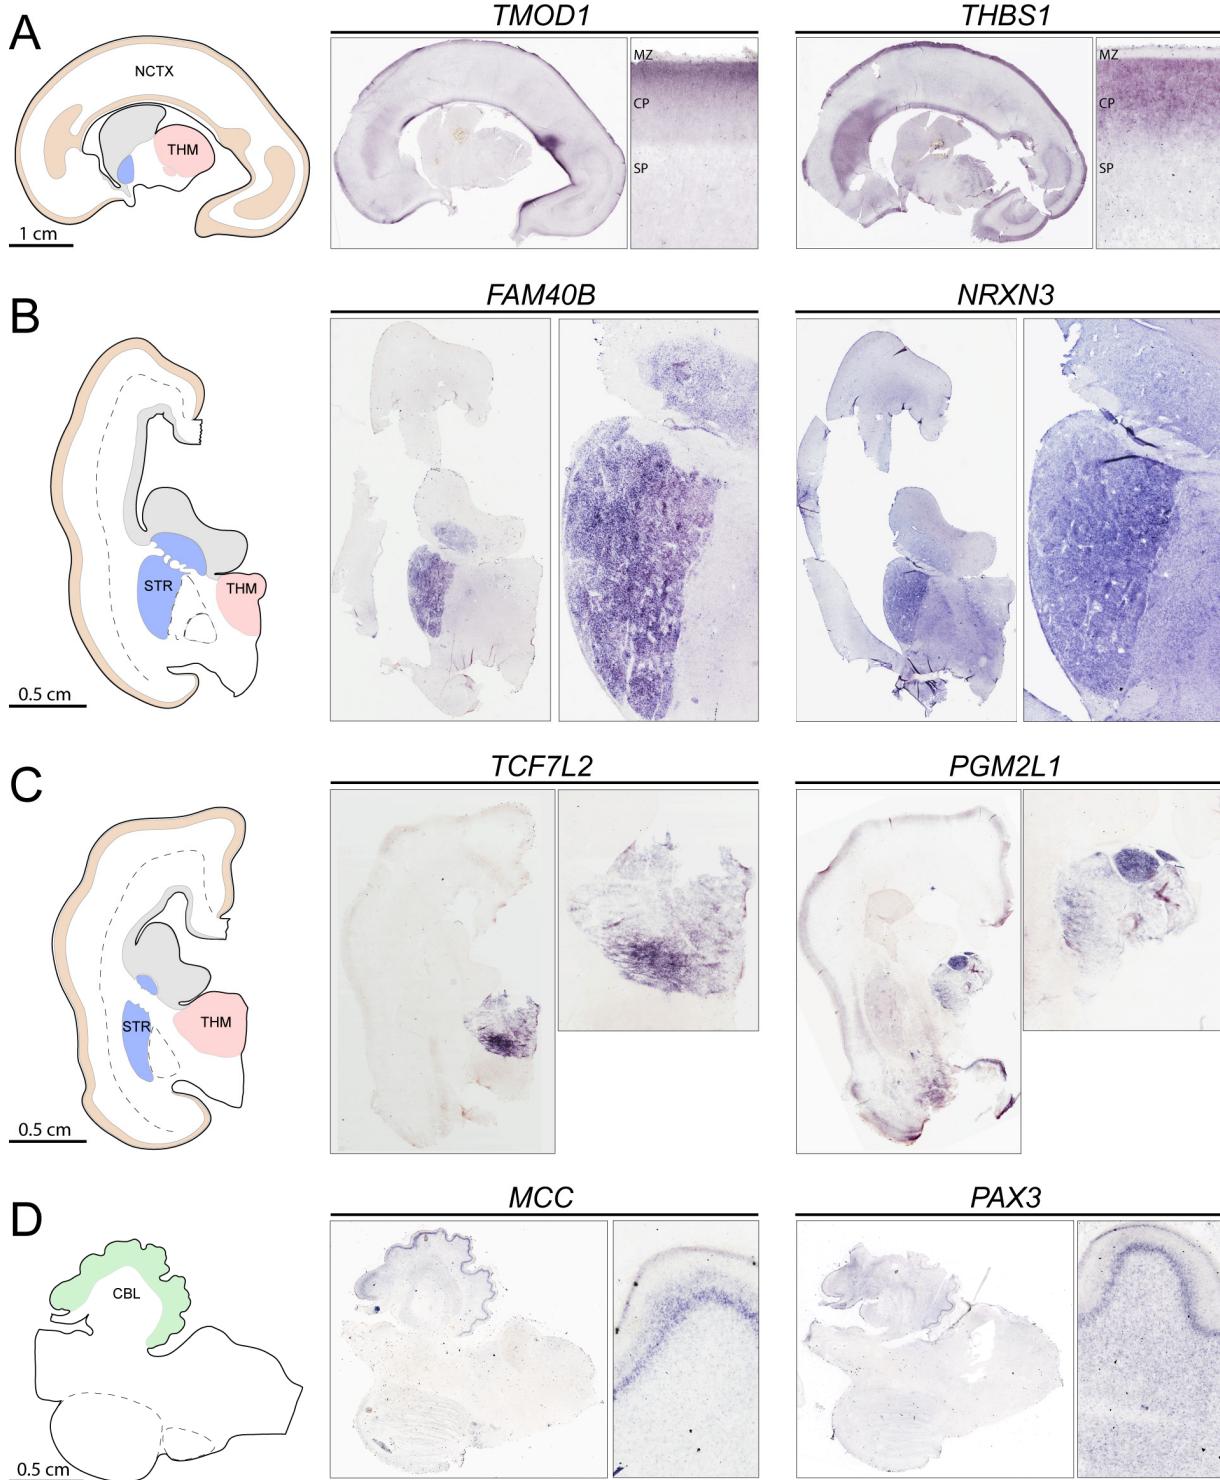

Supplemental Figure 4. Comparison of Exon 1.0 ST and U133 Plus 2 GeneChip Microarrays Using Human Fetal Brain Tissue

The Exon Array features more comprehensive coverage of the human genome than previous generations of arrays (e.g., 1.4 million probesets on the Exon Array, versus 54,000 probesets on the U133 Plus 2 array). However, because of its novelty, the Exon Array lacks a comparable accumulation of biological validation. Therefore, to compare the old 3'-biased array platform with the new exon-based design specifically in terms of detecting gene expression differences in fetal human brain, we hybridized selected samples to both Exon and U133 arrays and compared gene expression levels and log ratios between DLPFC, VLPFC, and OCC. These plots show signal log ratios for DLPFC (red) and VLPFC (green) versus OCC. The two platforms were well correlated in all comparisons ($R^2 > 0.5$), providing us with confidence in making meaningful comparisons between Exon Array and extant U133 data from adult human brain, as well as from other tissues and species (see, e.g., Table S11). In addition to this analysis, other published studies using human adult brain and other non-neural tissues have since demonstrated the reliability of the Exon Array platform and its performance in comparison to the U133 Plus 2 Array (Abdueva et al., 2007; Kapur et al., 2007; Clark et al., 2007; Gardina et al., 2006).

Supplemental Figure 5. Principal Component Analysis of Exon Array Core Transcripts

We performed principal component analysis (PCA) of all core transcripts on the Exon Array to assess variability of the data across brain regions, individuals, and hybridizations. Batch effect removal was performed in Partek GS to remove effects of hybridization date or brain specimen (inter-individual variations). Following batch effect removal, separation between individuals was reduced (compare A and C), while separation between brain regions was improved, especially for subcortical areas (compare B and D). PCA confirmed that inter-individual differences had a smaller effect on gene expression data across all 17,000+ core transcripts than did variation between brain regions, especially between NCTX and sub-cortical areas (compare C and D). The same data in D is shown in E and F with axes rotated to better reveal the separation between brain regions. Finally, ellipses in F show that three NCTX samples lie more than three standard deviations from the cluster center, suggesting potential outlier status. ANOVA analysis excluding these samples did not alter the results for the most significantly DEX genes. Notably, PCA of all core transcripts did not segregate NCTX areas, although some clustering of individuals was apparent, consistent with the observations of Khaitovich et al. (2004) that inter-individual gene expression differences outweighed inter-areal differences in adult human cortex.

Supplemental Figure 6. *In Situ* Hybridization of Selected Exon Array Candidate Genes

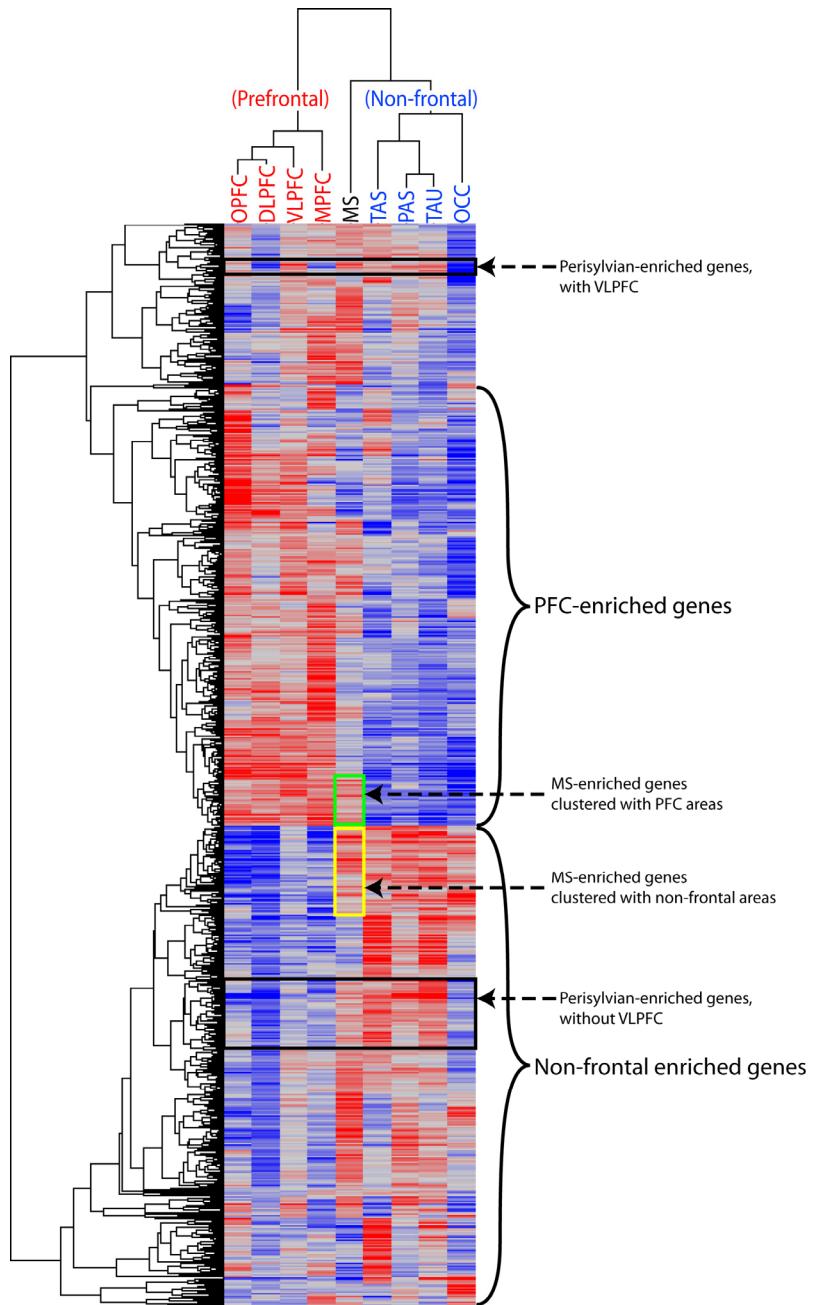

We selected candidate genes from the clusters shown in Figure 2 for further confirmation based on putative function, apparent divergence from expression in mouse, gene novelty, and maximum and fold-change expression levels. In the schematic illustrations at left, the cortical plate (CP) is shaded in beige, the caudate and putamen (STR) in blue, the thalamus (THM) in pink, and the cerebellar cortex (CBL) in green. The grey areas in (A-C) are the forebrain neurogenic regions, the cortical ventricular zone and the ganglionic eminence. (A) and (D) are sagittal sections through the forebrain and cerebellum/brainstem, respectively, while (B) and (C) are coronal sections through the forebrain, with (B) more rostral than (C). All sections are from late mid-fetal brain specimens (19 to 22 wg).

(A) *TMOD1* and *THBS1* were 6.8- and 7.5-fold enriched in NCTX by Exon Array analysis, respectively, and this specific enrichment was confirmed by qRT-PCR ($p < 0.0005$). *In situ* hybridizations shown here indicate that *TMOD1* is specifically enriched in the upper CP, while *THBS1* is expressed throughout the CP, and neither gene is noticeably expressed in the STR or THM. Tmod1 is an actin regulatory protein and a possible transcriptional target of the non-canonical Wnt pathway. Although it has been shown to be expressed in neurons in the adult mouse forebrain, its specific role in neuronal development or function remains unknown. *THBS1* is a member of a family of genes involved in synaptogenesis and plasticity, two others of which have been implicated in primate cortical evolution.

(B) *FAM40B* was one of the most enriched genes in STR (~24-fold), while *NRXN3* was also highly enriched in this structure (~4-fold). Both were confirmed by qRT-PCR as well as ISH, with the *in situ* shown here suggesting restricted expression in the putamen and caudate nucleus. *FAM40B* is a completely unknown transcript encoding a protein with multiple predicted transmembrane domains. According to the Allen Brain Atlas, its mouse homolog is enriched in the upper cortical pyramidal layers, CA fields of the hippocampus, the striatum, and the Purkinje cell layer of the cerebellum. *NRXN3* is one of the lesser known members of the neurexin-neuroligin gene families involved in cell adhesion at the synapse. *NRXN3* polymorphisms have been linked to opioid and alcohol dependence in humans, and the mouse homolog has been shown to be upregulated in the striatum of animals developing cocaine addiction. *NRXN3* has also been shown to be alternatively spliced; our Exon Array and qRT-PCR data suggest that while the full-length isoform is enriched in STR, as shown here also by ISH, the truncated isoform (NM_138970) is specifically enriched in THM relative to other brain regions (data not shown).

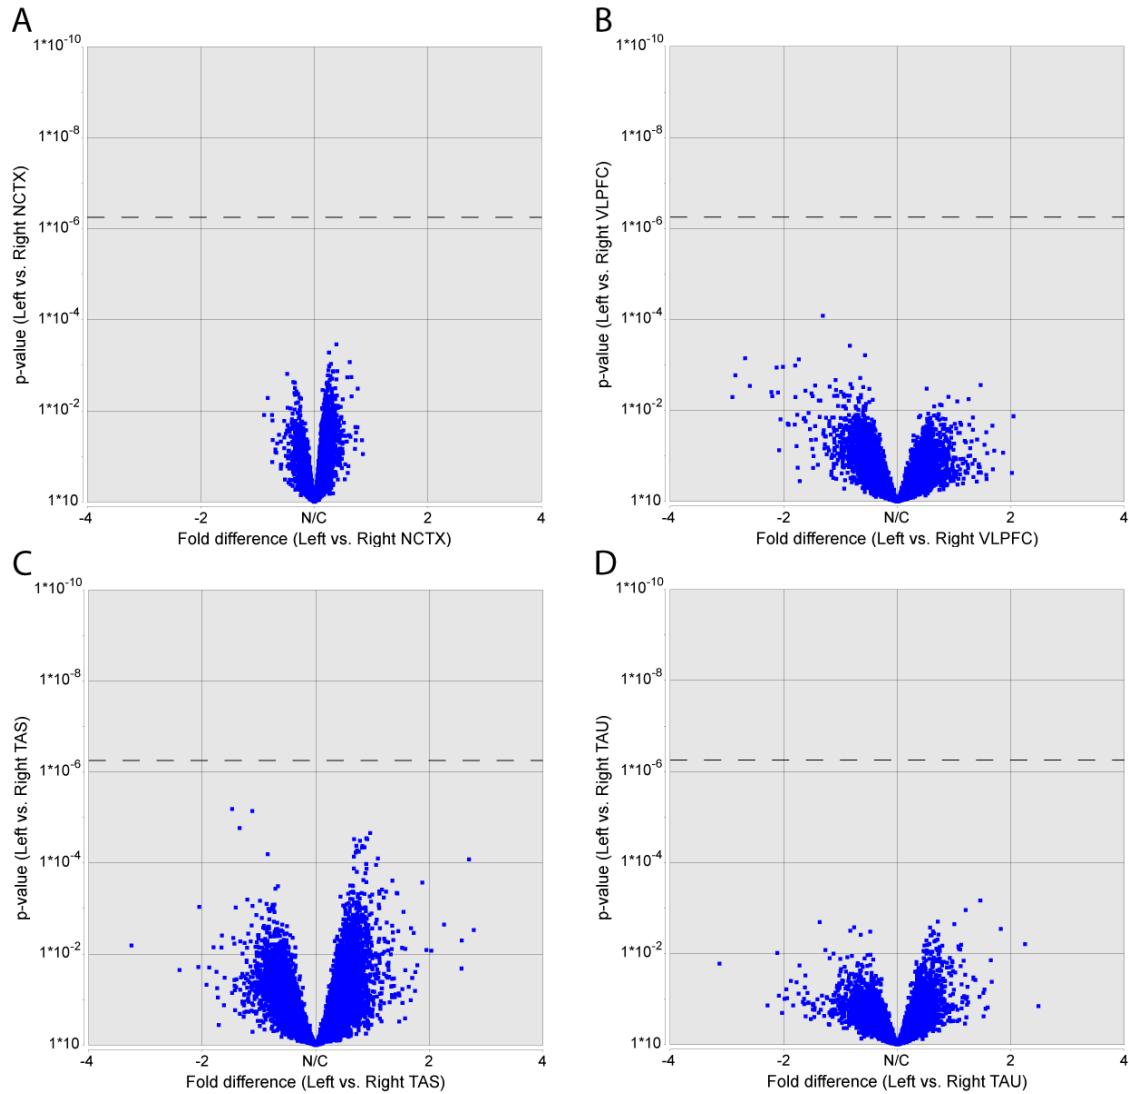

(C) *TCF7L2* was one of the most highly THM-enriched genes (>30-fold), consistent with a previous report of its significant enrichment in the macaque monkey thalamus (Murray et al., 2007). ISH shows this Wnt-pathway transcription factor to be specifically enriched in the ventrolateral thalamus. *PGM2L1* was ~4-fold enriched in THM by Exon Array analysis and confirmed by qRT-PCR. ISH shows specific enrichment in the dorsolateral nucleus. *PGM2L1* encodes an enzyme involved in glucose metabolism, and has not yet been studied in the context of the nervous system.

(D) *PAX3* and *MCC* (*mutated in colorectal cancer*) were 6.5- and 2.8-fold enriched in CBL by Exon Array analysis and were confirmed by qRT-PCR (Figure 2 and data not shown) and ISH.

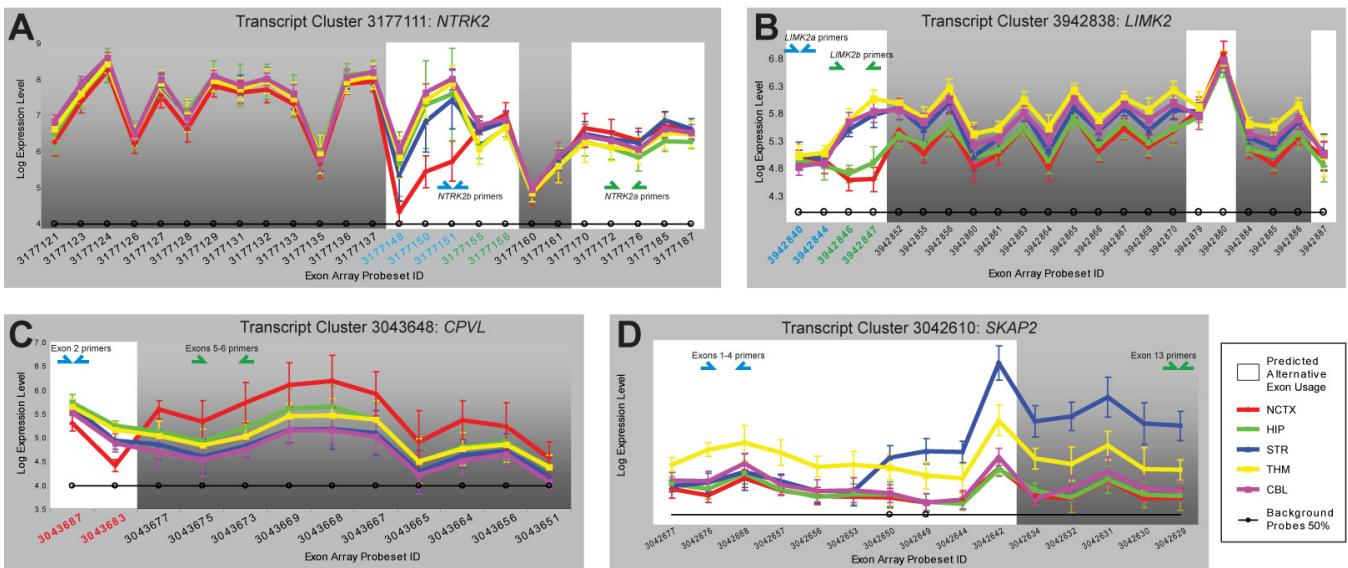

Supplemental Figure 7. Differential Gene Expression in the Mid-Fetal Human Neocortex

Unsupervised hierarchical cluster analysis of 1,753 genes differentially expressed ($FDR < 0.01$) within the late mid-fetal human neocortex. Clustering of areas suggests a broad separation of PFC ($r=0.37$) from non-frontal ($r=0.25$) cortical areas. The most similar areas in this analysis were TAU+PAS ($r=0.67$) followed by OPFC+DLPFC ($r=0.57$). The MS sample, taken from the border area of the frontal and parietal lobes, does not correlate with either PFC or PAS; rather, genes enriched in MS are divided into those that cluster with PFC and those that cluster with non-PFC areas, reflecting the mixed frontoparietal nature of the sample. These results prompted us to perform the additional, targeted analyses shown in the main Figure 3. Red is higher expression, blue is lower expression, with genes individually median-centered at grey.

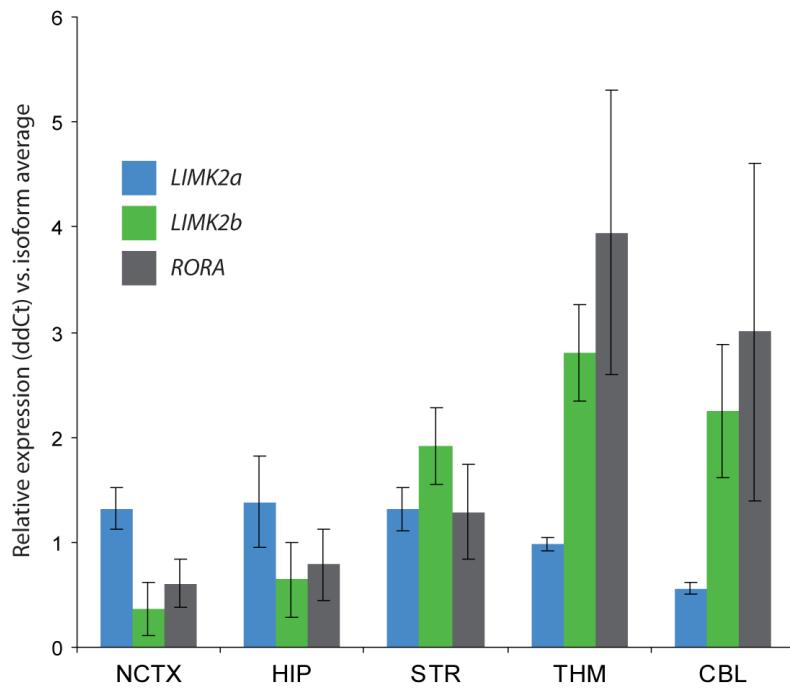

Supplemental Figure 8. Population-Level Left-Right Symmetry of Gene Expression in the Mid-Fetal Human Neocortex

Volcano plots depicting the range of fold-differences and uncorrected p-values in NCTX as a whole (A) and in representative perisylvian cortical areas (B-D). In these as in all other NCTX areas and brain regions tested, no genes showed significant left-right differential expression, even after the most lenient correction for multiple comparisons. Dashed lines indicate a corrected p-value of 0.01 (step-up FDR).

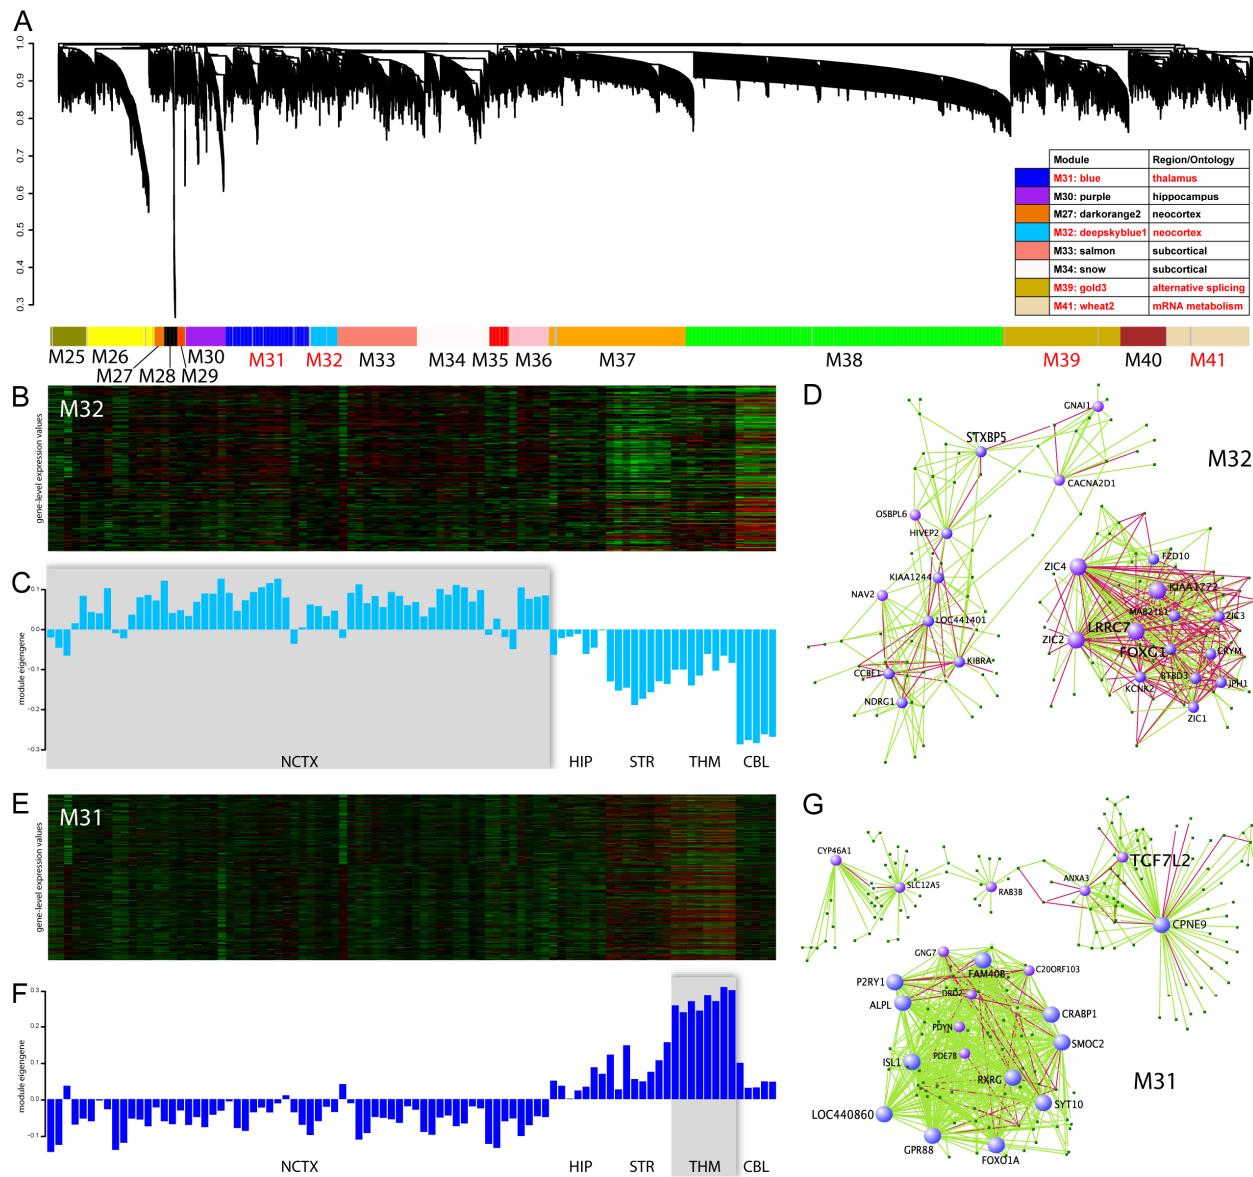

Supplemental Figure 9. Identification of Differential Alternative Splicing Across Brain Regions by Exon Array Probeset-Level Expression Data

Plotted are expression levels (y-axis) for each probeset (x-axis) for genes with a statistically significant interaction between probeset expression (“exon usage”) and brain region. Non-parallel probeset expression levels, highlighted in white, indicate region-dependent differential splicing of the corresponding exons. Blue and green arrows indicate the exon locations of isoform- or exon-specific qRT-PCR primers. Plots are adapted from the XRAY auto-generated output.

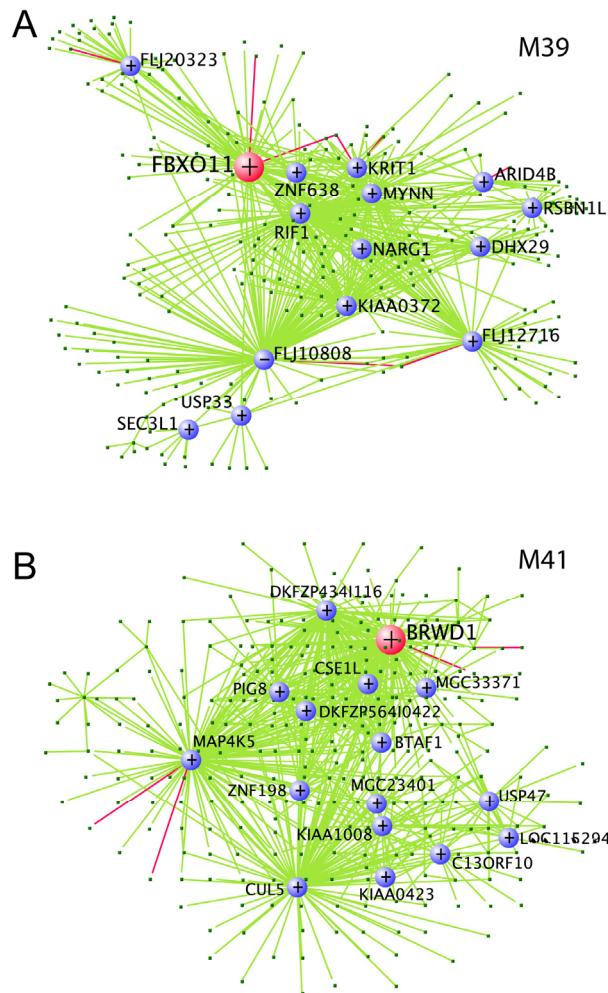

Supplemental Figure 10. Differential Alternative Splicing of *LIMK2* Corresponds to Expression of its Putative Regulator *RORA*

Confirmation by qRT-PCR of the regional differential alternative splicing of *LIMK2*, together with qRT-PCR confirmation of differential expression of *RORA*. Enrichment of *RORA* in THM and CBL correlates with *LIMK2b*, but not *LIMK2a*. Interestingly, the original report of alternative splicing of *LIMK2* also reported evidence for regulation of the *b*, but not the *a* isoform by *RORA* (Nomoto et al., 1999). These data suggest that Exon Array alternative splicing analysis may be useful in predicting or refining isoform-specific transcriptional regulatory relationships. Data are mean \pm SEM.

Supplemental Figure 11. Network Structure of Gene Co-Expression Relationships in the Mid-Fetal Human Brain

Weighted gene co-expression network analysis (WGCNA) was performed on gene-level expression data to identify modules of co-regulated genes within different brain regions. **(A)** Clustering of genes based on topological overlap (TO) identifies modules of co-regulated genes in the developing human brain. Modules are defined by dynamic tree cutting. **(B-D)** Module M32 corresponds to NCTX and contains many genes specifically enriched or suppressed in NCTX. The hub gene *LRRK7* encodes a well-known post-synaptic density protein, also known as *Densin-180*, involved in dendritic outgrowth and arborization. This module also contains a disproportionate number of TALE-type homeobox transcription factors, including *MEIS1* and the *Irquiois homeobox* family members 1, 2, 3, and 5 (Table S12). **(E-G)** Module M31 corresponds to THM and contains a high proportion of THM-enriched genes. The hub gene *TCF7L2* is a transcription factor in the Wnt signaling pathway and has been found to be enriched in specific thalamic nuclei in adult rhesus macaque. Interestingly, this module contains at least 13 other genes putatively involved in the Wnt pathway (Table S13), suggesting a significant involvement of this pathway in human THM development.

Supplemental Figure 12. Alternative Splicing and mRNA Metabolism Network Modules

Only two modules from the network pictured in Figure S10A contained more genes that were DAS than those that were DEX, suggesting a common program of alternative splicing may underlie these modules' transcriptional co-regulation. **(A)** Gene Ontology analysis of module M39 revealed a significant enrichment of terms related to mRNA splicing and processing. Genes in this module included several HNRNP, DEAD box, and Splicing Factor family genes, as well as the neuronal-specific splicing factor *PTBP2* (Table S16). **(B)** Module M41 was annotated with many of the same mRNA splicing and processing GO terms. However, the most significantly enriched terms were more broadly related to mRNA metabolism and transcriptional regulation, suggesting a more general transcriptional machinery network.

Supplemental Experimental Procedures

Human Brain Specimens and Tissue Processing

This study was carried out using post-mortem human brain specimens collected from the Human Fetal Tissue Repository at the Albert Einstein College of Medicine (AECOM), according to guidelines on the research use of human brain tissue and approval by the Human Investigation Committees from the AECOM and Yale University School of Medicine. For each tissue donation, appropriate maternal written informed consent was obtained and all available non-identifying information was recorded. The fetal age was determined by the date of last menstruation, ultrasonographic scanning, and/or foot length. Only brains with no signs of malformations or brain lesions were collected (Table S1). Of these, four mid-fetal brains were inspected for gross anatomical defects, and microdissected to isolate samples from specific brain regions. We chose these brain regions based on their functional importance and our confidence in identifying them at the late mid-fetal stage, and with the additional goals of limiting the time of dissection and thus the total postmortem delay, as well as the maximum difference in dissection time between brain areas. Dissected tissue was fresh-frozen in TRIzol for RNA and DNA extraction, with a post-mortem interval of less than 1 hour. The tissue remaining after microdissection was fixed, cryoprotected, frozen, and stored at -80°C. Tissue sections were analyzed for neuropathological or developmental defects. In addition to normal cellular distribution identified by Nissl staining, we used various immunohistochemical markers to confirm the presence of all major neuronal and glial cell types present at this developmental age (Figures S1-S2 and data not shown).

RNA Processing and Affymetrix Exon Array Hybridization

Total RNA was isolated using TRIzol and further purified using the Qiagen RNeasy kit. The quality of total RNA was determined by A260/A280 ratio to be at least 1.8, and further checked by electrophoresis on an Agilent Bioanalyzer. Ten µg of very high quality total RNA from each sample was provided to the Yale Neuroscience Microarray Center facility for cDNA labeling, hybridization, and data analysis.

Preparation of labeled cDNA for hybridization onto Affymetrix GeneChips followed the recommended Affymetrix protocol. An aliquot of 1 µg of sample was subjected to ribosomal RNA (rRNA) reduction. Quality of the rRNA reduction was determined by comparing the reduced RNA to the total RNA on the Bioanalyzer. Double-stranded cDNA and cRNA were synthesized. After the purification of cRNA, the first strand of cDNA was synthesized and fragmented to the size of 35 to 200 bases. The fragmented sample was then terminally labeled with biotin. Integrity of cDNA and fragmented cDNA was assessed by running aliquots on the Bioanalyzer before proceeding.

The entire fragmented sample was combined with a hybridization cocktail and loaded onto the Exon 1.0 ST Array. The hybridization cocktail contains control oligonucleotide B2 and 20X eukaryotic hybridization controls (bioB, bioC, bioD, Cre). These reagents serve as internal controls for hybridization efficiency. The arrays were hybridized for 16h at 45°C in a rotisserie oven. After hybridization, arrays were washed using the Affymetrix fluidics station and stained with streptavidin-phycerythrin according to the Affymetrix technical manual. Washed arrays were scanned on an Affymetrix GeneChip Scanner 3000, and the output files visually inspected for hybridization artifacts. The quality of the data was evaluated by checking the following quality control parameters:

Hybridization Controls: Presence of spiked-in control cRNAs bioB, bioC, bioD, and Cre serve as positive controls for hybridization. The data was considered acceptable if the hybridization intensities for these controls were present in increasing amounts, bioB being the lowest and Cre the highest.

Labeling Controls: Poly-A RNA controls are added at the beginning of the process to assess the whole target labeling process. The genes used for labeling controls are *in vitro* synthesized from *B. subtilis* and are absent in eukaryotic samples. These genes are lys, phe, thr, and dap.

Histology and Immunohistochemistry

Additional specimens obtained at AECOM were collected in cold DEPC-treated phosphate buffered saline (D-PBS) and separated from surrounding tissue. To obtain coronal tissue sections, specimens were immediately dissected into approximately 1 cm thick slabs and fixed in 4% (w/v) paraformaldehyde (PFA)/D-PBS for 36 hours at 4°C. To obtain sagittal tissue sections, specimens were cut at the level of the midbrain to separate the brain stem and cerebellum from the cerebrum. Following fixation tissue was cryoprotected in graded sucrose solutions [10%, 20%, and 30% (w/v) in D-PBS] at 4°C, embedded in Tissue-Tek O.C.T. (Sakura Finetek), frozen at -40°C in 2-methylbutane (J.T. Baker), and stored at -80°C. Coronally or sagittally oriented tissue sections (30 µm and 60 µm thick) were prepared using a Leica CM3050S cryostat and mounted onto Superfrost/Plus slides (Fisher Scientific Co.) or stored as free-floating sections in D-PBS at 4°C. The following primary antibodies with listed host animal, dilution, and source information, were used in images shown in this manuscript: anti-BCL11B (Rat, 1:250, Abcam/ab18465), anti-CNTNAP2 (Rabbit, 1:500, US Biological/C2089), anti-FOXP2 (Rabbit, 1:100, Rasin et al., 2007; Rabbit, 1:150000, Abcam/ab58599), anti-GABA (Rabbit, 1:2000, Sigma/A2052), anti-GFAP (Guinea pig, 1:500, Advanced ImmunoChemical/031223), anti-NeuN (mouse, 1:500, Chemicon/MAB377), anti-POU3F3 (Goat, 1:100, Santa Cruz Biotechnology/sc-6028), anti-RELN (Mouse, 1:100, gift of M. Ogawa; Ogawa et al., 1995), and anti-SOX5 (Goat, 1:100, Santa Cruz Biotechnology/sc-17329).

For 3,3'-diaminobenzidine (DAB; a chromogen) immunohistochemistry (IHC), slide mounted (30 or 60 µm) or free-floating (60 µm) tissue sections were first washed in PBS and quenched with 1% hydrogen peroxide in PBS, to block endogenous peroxidase activity. Next, the sections were washed in PBS and incubated in blocking solution (BS) containing 5% (v/v) normal donkey serum (Jackson ImmunoResearch Laboratories), 1% (w/v) bovine serum albumin, 0.1% (w/v) glycine, 0.1% (w/v) L-lysine, and 0.4% (v/v) Triton X-100 in PBS for 1 hr at room temperature. Sections were then incubated for 20 to 36 hrs at 4°C in primary antibodies diluted in BS. The sections were incubated in the appropriate donkey biotinylated secondary antibodies (Jackson ImmunoResearch Labs) diluted 1:250 in BS for 1.5-2 hrs at RT. Following washing in PBS, sections were incubated in avidin-biotin-peroxidase complex (Vectastain ABC Elite kit; Vector Laboratories) for 1 hr at RT. Sections were washed in PBS (3 x 15 min) and incubated for 5 min in 20 ml of PBS containing 0.05% (w/v) DAB, 0.04% (w/v) ammonium chloride, 0.5-1 mg glucose oxidase type VII, and 80 µl of 0.05M nickel ammonium sulfate in 0.2M acetate buffer (pH 6.0). The peroxidase reaction was started by adding 400 µl of 10% (w/v) D-glucose/PBS and stopped 5-10 min later by washing in PB. Alternatively, developing was performed using a DAB peroxidase substrate kit according to the manufacturer's protocol (catalog #SK-4100; Vector Laboratories). Finally, sections were dehydrated, mounted on Superfrost Plus charged slides and coverslipped with Permount (Fisher Scientific Co.).

For triple labeled immunofluorescence staining of CNTNAP2, GFAP, and NeuN, tissue sections were incubated with appropriate donkey secondary antibody conjugated to Cy2, Cy3, or Cy5 (Jackson ImmunoResearch Labs). Single optical images were collected on a Zeiss LSM 510 laser-scanning microscope.

Illumina DNA Microarray Quality Control

Genomic DNA was extracted using the AllPrep Mini Kit (Qiagen) according to the manufacturer's instructions. Quality of genomic DNA was confirmed by running an agarose gel (150 ng/sample on a 1% gel). Only samples that had fragments longer than 2 kb were used for Illumina genotyping assays. We performed genotyping with the Illumina Infinium HumanHap 650Y BeadChips, with probes at 660,755 spots on the genome and a mean inter-probe spacing of 4.5kb, using methods previously described (Peiffer et al., 2006). The Illumina chips were scanned with a BeadArray Reader, a confocal fluorescent scanner that excites the fluorophores generated during the signal amplification of the allele-extension products on the BeadChips. The image intensities and genotypes were extracted using

Illumina's BeadScan software. Our four specimens were compared to a standard set of intensities from 120 HapHap samples for the determination of any changes in DNA copy number for each SNP. All chips had call rates above 95%, indicating high data quality. We used both a published algorithm, PennCNV (Wang et al., 2007), and our own in-house software, to predict CNVs from these data.

Exon Microarray Data Analysis

All microarray data analyses were performed on Dell desktop computers. Affymetrix CEL files were imported into Partek Genomics Suite (Partek GS; Partek, Inc.) using the default Robust Multichip Average (RMA) settings: RMA background correction, quantile normalization, GC content adjustment, mean probeset summarization, and log₂ transformation. PCA, ANOVA, and t-tests reported here were performed using the core, unbounded probesets, as defined by Affymetrix, which were averaged to yield gene summary scores for 17,421 transcript clusters. All ANOVAs included brain specimen and hybridization date as cofactors to exclude batch effects and individual genetic variation. In addition, repeated analyses were performed after excluding potential outliers (three NCTX samples more than three standard deviations from a PCA cluster center, based on all core transcripts; see Figure S5). These analyses marginally reduced the total number of significant results, but did not affect any of the highly DEX genes discussed in detail in this paper.

Partek GS was similarly used to prepare data for the UCSC Human Genome Browser track, as follows: “full” probesets were imported using RMA settings without log transformation, and untransformed expression values from each array were divided by values from an array hybridized with pooled RNA from all samples of the same brain. This ratio was then log₂-transformed to generate the “signal log ratio” (SLR) values presented on the Genome Browser track. SLR values were calculated in this way to be consistent with the “Affy Exon” tissue panel expression track supplied by Affymetrix.

Similarly, the Excel Array Analysis software package (XRAY; Biotique Systems, Inc.) imported core probesets from Affymetrix CEL files using full quantile normalization, and performed GC content-based probe screening, log transformation, and probeset summarization. Detection above background (DABG) was performed at both the probe and the probeset level using GC-matched background probes, and low-variance probesets were excluded. In addition, individual probesets not expressed significantly above background were excluded from tests for alternative exon usage, as these lead to false positives for tissue-specific alternative splicing. XRAY was used to perform a mixed model, nested analysis of variance (ANOVA) to identify genes differentially expressed (DEX) or alternatively spliced (DAS) across brain regions or neocortical areas. Resulting p-values were corrected for multiple comparisons using the Benjamini and Hochberg False Discovery Rate (FDR) method (Benjamini and Hochberg, 1995). See the auto-generated XRAY methods and results paper, available at www.sestanlab.org or www.humanbrainatlas.org, for more XRAY analysis details.

Hierarchical Cluster Analysis

Unsupervised hierarchical clustering was performed in Cluster 3.0 (bonsai.ims.u-tokyo.ac.jp/~mdehoon/software/cluster; de Hoon et al., 2004). Gene-level group median log expression values returned by XRAY for DEX and DAS genes were mean centered across brain regions, and both genes and brain regions were clustered using uncentered Pearson correlation and average linkage. Heatmaps were generated in Java Treeview (jtreeview.sourceforge.net; Saldanha, 2004) and used to identify clusters of correlated transcripts most highly specific for each brain region or neocortical area. Clusters shown in Figures 2 and 3 and listed in the Supplemental Tables were restricted to a minimum correlation of 0.75.

Quantitative Real-Time RT-PCR

Primers for quantitative real-time RT-PCR (qRT-PCR) were designed using the Primer3 software (fokker.wi.mit.edu/primer3/input.htm), or the Roche Universal ProbeLibrary Assay Design Center

(www.roche-applied-science.com/sis/rtpcr/upl/index.jsp), which designs intron-spanning primer pairs whenever possible. All primers were blasted against the Ensembl human cDNA database using BlastView (www.ensembl.org/Homo_sapiens/blastview) to check for non-specific binding.

Whenever possible, alternative exon usage was confirmed by designing primers specific to each known or predicted alternative splice isoform. In the absence of known or computationally predicted isoforms, DAS results were confirmed by comparing primers specific to the known isoform with primers targeting an area common to the known and the predicted transcript.

Template cDNA was synthesized from the same total RNA prepared for Exon Array analyses using the SuperScript III First-Strand Synthesis System (Invitrogen). Real-time PCR was performed on an ABI PRISM 7900 Real Time PCR System (Applied Biosystems) using SYBR Green as the detection method (Power SYBR Green PCR Master Mix, Applied Biosystems). Semi-quantitative RT-PCR, for gel images shown in Figure 6, was performed with the same primers and template, using GoTaq PCR Master Mix (Promega) and a Bio-Rad DNA Engine thermal cycler. PCR products were run on 2% agarose gel with ethidium bromide, photographed with UV illumination, and images inverted in Photoshop.

For quantitative PCR, Ct values greater than two standard deviations from the mean for a given primer pair were excluded as outliers. Duplicate or triplicate reactions were then averaged, and fold-change was calculated by the ddCt method relative to the average dCt across all samples for a given primer pair, with GAPDH as the reference for all genes. DAS candidates were considered confirmed if a two-way ANOVA of sample (brain region or NCTX area) and splice isoform (primer pair) yielded an interaction with p<0.05.

***In Situ* Hybridization Probe Synthesis and Labeling**

For ISH probe synthesis, we first PCR-cloned the target DNA, between 300-1000 bp, into the pCRII vector, which contains SP6 and T7 RNA polymerase promoter sites for *in vitro* transcription, and amplified the plasmid in competent E. coli cells overnight (TOPO TA Cloning Kit with Dual Promoter; Invitrogen). The plasmid was sequenced to confirm the sequence and determine the direction of the DNA insert, and thus which RNA polymerase to use for *in vitro* transcription. The plasmid was then purified and linearized with a restriction enzyme that leaves a 5' overhang, run on an agarose gel to confirm complete digestion, and re-purified with the QIAquick PCR purification kit (Qiagen). The linearized plasmid was resuspended in non-DEPC-treated, nuclease-free water at a concentration of 200-250 µg/ml.

RNA probe synthesis was carried out using the DIG RNA labeling kit (Roche). Briefly, an *in vitro* transcription mixture was prepared with one µg linearized DNA plasmid; two µl 10x transcription buffer; two µl DIG RNA labeling mix; one µl RNase inhibitor; two µl RNA SP6 or T7 polymerase (depending on the direction of the DNA insert); and non-DEPC-treated nuclease-free water to a final volume of 20 µl. After 2 hours at 37°C, an aliquot was run on a native agarose gel to confirm the RNA product. Reaction was then incubated with 2 µl DNase I (RNase free) for 15 min at 37° to remove template DNA, followed by addition of 2 µl of 0.2 M EDTA (pH 8.0) to stop the reaction. Excess free nucleotides were removed by Micro Bio-Spin 30 RNase-free column (Bio-Rad). Labeled RNA probe was run on a native agarose gel to determine its quality and quantity.

***In Situ* Hybridization**

Sections were cut on a Leica cryostat at -20°C; 60 µm sections were immediately mounted on cold, charged Superfrost 2x3" slides, brought to room temperature, and hybridized. Thicker sections, up to 150 µm, were hybridized free-floating in 6-well plates or 60 mm dishes and mounted later.

Sections were washed in PBS at room temperature (rt) for 5 min, post-fixed in 4% PFA for 15 min at rt, washed again in PBS 3x5 min, and pre-hybridized in hybridization solution at 70°C for 30 min. No proteinase K treatment was necessary for embryonic brain tissue, which is relatively porous. DIG-

labeled probe was diluted to 0.3 μ g/ml in hybridization buffer, denatured at 75°C for 5 min, and applied to the sections. Sections were hybridized at least overnight at between 60-70°C, depending on probe GC content, specificity of signal, and target abundance.

After washing 3x15 min in TBST at rt, sections were then incubated in AP-conjugated anti-DIG antibody (1:5000 in TBST; Roche) overnight at 4°C. Sections were again washed 3x15 min in TBST and 10 min in staining buffer at rt. Staining buffer was then replaced with fresh staining buffer with PVA and 1:50 NBT/BCIP stock solution (Roche), and sections were incubated in the dark at rt, or overnight at 4°C, until the color reaction was complete. Finally, sections were washed in stop-TE buffer and fixed again with 4% PFC to stop the color reaction, washed in PB, and free-floating sections mounted onto charged Superfrost 2x3" slides.

Gene Ontology Annotation Analysis

Annotation analysis was performed using the NIAID web-based DAVID software (david.abcc.ncifcrf.gov; Dennis et al., 2003). The following categories were used to annotate lists of DEX genes: GO Biological Process, Molecular Function, and Cellular Component terms; SwissProt and InterPro protein domain and family terms; KEGG pathways; BIND protein-protein interactions; and OMIM genetic disorder associations. The EASE score, a modified Fisher's exact test, is used to evaluate the overrepresentation or enrichment of a given annotation in a gene list, in comparison to a background gene list (Hosack et al., 2003). In our case, the background consisted of ~17,000 genes represented by the "core" probesets on the Affymetrix Exon Arrays. The DAVID web tool also enables Functional Annotation Clustering, which takes the annotations of a gene list and clusters terms with overlapping member genes. This reduces redundancy across annotation sources, as well as providing insights into relationships between annotations (e.g., the zinc finger protein domain annotation clusters together with the Biological Process transcriptional regulation term, suggesting that zinc finger proteins tend to be transcription factors or co-factors). The geometric mean of the EASE enrichment scores of the terms in a cluster, called the Group Enrichment Score, is then used to reflect the overall enrichment of a biological function or theme in the gene list. See the DAVID website for further details.

Weighted Gene Co-expression Network Analysis

Gene summary scores were calculated in Partek for all core transcript clusters, and all pairwise Pearson correlations between genes were calculated. Three samples – 18 w.g. left HIP, 19 w.g. left DLPFC, and 19 w.g. right MS – were flagged as potential outliers and excluded from WGCNA. For each gene, the sum of its correlations with all other genes is called connectivity, k , and represents its connectedness to all other genes. Next, each gene's set of correlations is compared to all other genes' sets of correlations, to calculate each pair of genes' *topological overlap* (TO), which represents the degree to which a pair of genes share the same correlations, or network "neighborhood." Hierarchical clustering is then used to group genes based on their TO into "modules," or networks, and intra-network connectivity (k_{in}) is recalculated for genes in a module based only on the other genes in the module. The genes with the highest k_{in} values are termed "hubs" of the network. Finally, the expression data for genes in a module are subjected to Singular Value Decomposition analysis, and the module eigengene, or first principal component, is plotted to visualize potential relatedness of the module to variables such as brain region, specimen, or hemisphere. Annotated R code used for our network analysis is available at www.sestanlab.org or www.humanbrainatlas.org. General information on network analysis methodology, as well as WGCNA software and R code, is available at www.genetics.ucla.edu/labs/horvath/CoexpressionNetwork. For more details see Horvath et al. (2006), as well as supplementary material published with Oldham et al. (2006) and Oldham et al. (2008).

Supplemental Table Descriptions

All tables are available as Excel spreadsheets at www.humanbrainatlas.org.

Table S1. Fetal human brain specimens. The first four specimens were microdissected for Affymetrix Exon Array profiling and qRT-PCR validation. Genomic DNA was also hybridized to Illumina genotyping arrays for copy number analysis (Table S2). Leftover tissue was fixed, frozen, and sectioned for histological and immunohistochemical analyses (e.g., Figures S1-S2). The additional thirteen mid-fetal human brains listed here were used for candidate gene validations by qRT-PCR, *in situ* hybridization, and/or immunohistochemistry (e.g., Figures 4 and S6). All specimens had post-mortem intervals less than one hour, and were free of gross morphological defects.

Table S2. Complete list of predicted copy number variations. This table shows the predicted CNVs with the chromosomal location, as well as the first and last SNP, for each brain used for Exon Array analysis. The type of putative CNV is indicated as follows: HOMODEL, homozygous deletion; HETDEL, heterozygous deletion; HETDUP, heterozygous duplication; AMPLIF, amplification. If the CNV hits a gene, it is listed as coding; if it hits an intron, it is listed as intronic; otherwise the CNV is labeled intergenic. Also, the overlap with known CNVs from the Toronto Database of Genomic Variants or Segmental Duplications is noted. The 18 wg specimen shows a higher number of CNVs likely due to its lower genotyping call rate (95%), which is known to introduce more false positive CNVs (Wang et al., 2007); all other chips are at 99% call rate. Total numbers of predicted CNVs for each brain are within the range of variation seen in a control set of 120 well-characterized HapMap individuals (Figure S3).

Table S3. Exon Array hybridizations and sample info. RNA isolated from each area illustrated in Figure 1 was hybridized independently from each of the four brains, with the following exceptions: left and right sides of the cerebellum were collected separately only from the 19 wg specimen; OPFC was obtained only from the 19 wg specimen.

Table S4. Numbers of expressed and region-specific genes. Tables display numbers of expressed (present), DEX, and DAS core transcripts from each of four distinct XRAY mixed model analyses of variance, as described in the main text.

Table S5. Numbers of genes and correlations of clusters illustrated in Figures 2 and 3. Uncentered Pearson correlations were obtained by unsupervised hierarchical clustering as described in the Supplemental Experimental Procedures.

Table S6. Gene lists for clusters illustrated in Figure 2.

Table S7. Gene lists for intra-NCTX clusters illustrated in Figure 3a.

Table S8. Gene lists for PFC clusters illustrated in Figure 3b.

Table S9. Additional DEX genes validated by qRT-PCR, ISH, and IHC.

Table S10. Perisylvian NCTX-enriched genes.

Table S11. Comparison with adult human brain microarray data. Roth et al. (2006) represents the most spatially comprehensive microarray analysis of human brain previously published. “Probe ID”

corresponds to the probeset ID from Affymetrix U133 Plus 2.0 arrays. ND, No Data: equivalent probesets not present or not analyzed, due to contraindications such as discontinued gene records.

Table S12. Comparison with published developing mouse cortex microarray data. ND, No Data: equivalent probesets not present or not analyzed, due to contraindications such as discontinued gene records or lack of homology.

Table S13. DEX genes with associated haCNSs, which are numbered as in Prabhakar et al. (2006). Genomic locations of haCNSs are in hg18 coordinates (NCBI build 36.1).

Table S14. Gene ontology functional annotation clustering.

Table S15. M32 (deepskyblue1): NCTX module.

Table S16. M31 (blue): THM module.

Table S17. M15 (cyan): PFC module.

Table S18. M24 (orange): non-PFC module.

Table S19. M39 (gold3): alternative splicing module.

Table S20. M41 (wheat2): mRNA metabolism module.

Tables S15 to S20 list all genes found in network modules described in the main text. In these tables, genes are sorted by kWithin-Connectivity, which represents the within-module connectivity or “hub status” of each gene. In addition, the total connectivity of the gene to the entire network is given (kTotal), as well as the correlation of the gene’s expression data to the module “eigengene,” or first principal component (eigencorr), and the significance of this correlation (eigenpval) which determines the module membership. Genes with negative correlations are indicated in red. Finally, at the right are appended the FDR-corrected p-values for module genes that were also DEX or DAS. All additional network modules are available at www.humanbrainatlas.org.

Table S1. Human Fetal Brain Specimens

	Code	Age (wg)	Fetal gender	Facial or bodily abnormalities	Gross brain abnormalities	Microscopic brain abnormalities	Chromosomal abnormalities	Maternal ethnicity	Maternal age (years old)	Maternal medical history	EtOH use (donor)	Cigarette and drug use (donor)

Table S4. Numbers of expressed and region-specific genes

Total "core" transcript clusters (genes) tested:			17,421	
Regional ANOVA	Number of genes expressed	% of core genes	Region-specific genes	% of core genes
Total	13,223	75.9%		
NCTX	8,876	51.0%	659	3.8%
HIP	9,586	55.0%	114	0.7%
STR	9,764	56.0%	83	0.5%
THM	9,866	56.6%	135	0.8%
CBL	10,020	57.5%	316	1.8%
DEX (FDR<1E-5)	4369	25.1%	(33% of genes expressed)	
DAS (FDR<1E-5)	3755	21.6%	(28% of genes expressed)	
<hr/>				
NCTX ANOVA	Number of genes expressed	% of core genes	Region-specific genes	% of core genes
Total	11,407	65.5%		
OPFC	10,135	58.2%	457	2.6%
MPFC	9,910	56.9%	50	0.3%
DLPFC	9,404	54.0%	4	0.0%
VLPFC	9,721	55.8%	6	0.0%
MS	9,812	56.3%	26	0.1%
PAS	9,549	54.8%	1	0.0%
TAS	9,686	55.6%	15	0.1%
TAU	9,500	54.5%	4	0.0%
OCC	9,497	54.5%	21	0.1%
DEX (FDR<1E-5)	471	2.7%	(4.1% of genes expressed)	
DAS (FDR<1E-5)	496	2.8%	(4.3% of genes expressed)	
DEX (FDR<0.01)	1753	10.1%	(15.4% of genes expressed)	
DAS (FDR<0.01)	828	4.8%	(7.3% of genes expressed)	
<hr/>				
PFC-grouped ANOVA	Number of genes expressed	% of core genes	Region-specific genes	% of core genes
Total	11,064	63.5%		
PFC	9,215	52.9%	484	2.8%
MS	9,487	54.5%	73	0.4%
PAS	9,260	53.2%	14	0.1%
TAS	9,135	52.4%	41	0.2%
TAU	9,344	53.6%	13	0.1%
OCC	9,123	52.4%	43	0.2%
DEX (FDR<0.01)	1425	8.2%	(12.9% of genes expressed)	
DAS (FDR<0.01)	827	4.7%	(7.5% of genes expressed)	
<hr/>				
Intra-PFC ANOVA	Number of genes expressed	% of core genes	Region-specific genes	% of core genes
Total	11,163	64.1%		
OPFC	10,061	57.8%	491	2.8%
MPFC	9,881	56.7%	93	0.5%
DLPFC	9,337	53.6%	12	0.1%
VLPFC	9,685	55.6%	10	0.1%
MS	9,763	56.0%	52	0.3%
DEX (FDR<0.01)	233	1.3%	(2.1% of genes expressed)	
DAS (FDR<0.01)	219	1.3%	(2.0% of genes expressed)	

Table S5. Numbers of genes and correlations for clusters illustrated in Figures 2 and 3

Figure 2	Pearson correlation	Number of genes	% of genes clustered (total: 1964)
Cluster 1: Cortex	0.71	109	5.5%
Cluster 1a: NCTX	0.76	52	2.6%
Cluster 1b: NCTX+HIP	0.78	57	2.9%
Cluster 2: HIP	0.80	109	5.5%
Cluster 3: STR	0.80	105	5.3%
Cluster 4: THM	0.80	137	7.0%
Cluster 5: CBL	0.81	140	7.1%

Figure 3a: NCTX	Pearson correlation	Number of genes	% of genes clustered (total: 1425)
Cluster 1: PFC (+MS)	0.91	29	2.0%
Cluster 2: PFC (+TAS)	0.82	28	2.0%
Cluster 3: Non-Frontal	0.86	18	1.3%
Cluster 4: TAU+TAS	0.90	25	1.8%
Cluster 5: PFC+TAS	0.89	15	1.1%
Cluster 6: OCC	0.82	11	0.8%

Figure 3b: Frontal Cortex	Pearson correlation	Number of genes	% of genes clustered (total: 233)
Cluster 1: PFC > MS	0.81	10	4.3%
Cluster 2: OPFC	0.94	5	2.1%
Cluster 3: OPFC+DLPFC+VLPFC	0.89	11	4.7%
Cluster 4: MPFC	0.87	13	5.6%
Cluster 5: MPFC+MS	0.85	13	5.6%
Cluster 6: VLPFC+MS	0.88	11	4.7%

Table S6. Gene lists for clusters illustrated in Figure 2

Cluster 1a: NCTX

Exon Array Transcript Cluster ID	Official Gene Symbol	Gene Name	Confirmation	Cytoband	RefSeq Accession	Entrez GeneID	Maximum Fold Change	corrected p-value (False Discovery Rate)	OMIM and Genetic Association Database annotations
